The time required for freezing the treated and the untreated areas did not vary significantly. Onset of freezing was heralded by a pricking or burning sensation and blanching of the skin. Within a few seconds, frost began to accumulate on the frozen skin and after ten seconds or more (depending on the intensity of the stimulus), a hard, frozen, cream-colored area, approximately 1.5 cm. in diameter, could be picked up between the fingers. This thawed in a matter of 60 seconds. Within a few minutes the frostbitten area became red and was sharply demarcated from the surrounding skin. In the untreated areas, a wheal invariably began to form within five minutes after removal of the stimulus, continued to swell until it reached a maximum in approximately 20 minutes, and gradually subsided in from one to four hours.

The wheals were graded I to III:

- I = Minimal or no wheal formation
- II = Slight to moderate wheal formation
- III = Marked wheal formation

The whealing was strikingly inhibited in the areas where the histamine antagonists had been introduced (Table I, Figure 1). Benadryl was slightly less effective than Pyribenzamine. Iontophoresis of normal saline had essentially no effect on wheal formation. When wheals did appear in the areas treated with the anti-histaminic agents, the time of appearance was invariably delayed. In most cases the duration and intensity of the cold stimulus were not sufficient to produce vesicle formation. In the few subjects in whom vesicles were produced they tended to be less severe in the areas treated with Benadryl or Pyribenzamine. In all instances the frostbitten skin was tender and

FIG. 1. THE INHIBITION OF FROSTBITE WHEEL ON THE THIGH BY PREVIOUS IONTOPHORESIS OF PYRIBENZAMINE HYDROCHLORIDE

S.C. = saline control, P. = pyribenzamine. Cold stimulus applied to both areas was jet of air at -40° F. for ten seconds.

somewhat painful for approximately 48 hours. The redness persisted for several days and was followed by scaling with eventual disappearance of the lesion in approximately three weeks. A comparison of the treated and untreated areas revealed no significant differences in the progress and ultimate outcome of the frostbite lesions.

SUMMARY AND CONCLUSIONS

1. Introduction of the histamine antagonists, Pyribenzamine hydrochloride and Benadryl hydrochloride, by an iontophoretic technique inhibited the formation of frostbite wheals in the human skin.

2. In these experiments no other effects of anti-histamine agents on the type or progress of localized frostbite lesions were observed.

3. It is concluded from these studies that histamine or a histamine-like substance is liberated in the human skin in the early stages of frostbite.

THE CONSTRUCTION OF NORMAL STANDARDS FOR CARDIAC OUTPUT IN MAN

By J. M. TANNER¹

(From the Laboratory of Therapeutic Research, University of Pennsylvania Medical School;
the Anthropological Laboratory, Department of Human Anatomy, Oxford University; and
the Sherrington School of Physiology, St. Thomas's Hospital, London University)

(Submitted for publication January 14, 1949)

INTRODUCTORY AND THEORETICAL

The present method of calculating normal cardiac output standards in man involves a fallacy, and has led in practice to erroneous conclusions (1). This is a serious matter for clinicians, since it has been shown by Starr that the first indications of symptomless heart disease may be given by abnormalities in cardiac output (2). Thus it is reasonable to suppose that in the next few decades the determination of cardiac output will become as common as that of basal metabolism, or more so. Consequently it is the object of this paper to present new standards, based on more adequate statistical methods. Use has been made of the data already in the literature, of a new series of 50 subjects so far only reported in abstract (3), and of partly published data on 174 normal individuals collected by Starr and his co-workers.

The introductory and theoretical part of this paper refers to the construction of cardiac output standards irrespective of the method used for measuring output. The main standards developed thereafter refer to the Starr ballistocardiograph; in this connection a new constant for use in the Starr formula for stroke volume is given. Lastly, some biometric relations between the various methods are examined, and as a result tentative recommendations with regard to cardiac catheterization data are made. There are at present insufficient catheterization data available on normal subjects from which to decide whether the same standards may be used as for the ballistocardiograph. In any case the ballistocardiograph seems the more appropriate instrument to use in determining whether a person is slightly abnormal or not.

Material

The material used in this analysis comes from three sources. Firstly, Table I reports measurements made personally with the ballistocardiograph on 50 healthy young men, when I was working in Dr. Starr's laboratory in 1943. In this study classification of physique by Sheldon's method (4) was undertaken and the somatotypes of the subjects are given in the last column; I am indebted to Dr. W. C. Dupertuis for help in this aspect of the work. Secondly, the raw data of the extensive ballistocardiographic series of 200 healthy persons reported by Starr and Schroeder in 1940 (5) have been available to me. This series is of particular value because the subjects have been followed for eight to ten years (2) and those now suffering from any cardiovascular disease have been eliminated from the present calculations, leaving 174 persons. Thirdly, in the last section of the paper, use has been made of all the substantial and detailed series of cardiac output data in the literature, including results obtained by catheterization, acetylene and ethyl iodide methods.

The reliability of cardiac output determinations and the relations between results obtained by different methods

Two points must be considered before undertaking a detailed and thus laborious biometric analysis of cardiac output data. First of all, it is clearly useless to construct standards for a physiological function which changes greatly from minute to minute or day to day in an unpredictable manner. We must first enquire what is the *reliability*²—the repeatability—of the measurement.

² *Reliability* must of course be clearly distinguished from validity. Reliability refers to how repeatable the measurement in question is, and validity to whether it in fact measures what it purports to measure. Clearly any

Standard Deviation	1.5	7.05	7.9	7.0/3.1	0.44	8.2	9.8	0.79	1.1	1.0	1.3

This point must be emphasized simply because, at least in its statistical aspects, it has been thoroughly neglected by physiologists and clinicians, who often instead assume their measurements to measurement which is not reasonably reliable cannot be valid, but the converse does not hold.

be a great deal more reliable than they really are. The simplest way of quantitating reliability is by giving the correlation coefficient between two determinations, the second taken a few minutes or days after the first. This test-retest correlation is known as the *coefficient of reliability*. Despite

its importance, it has only been reported for one cardiac output method, the Starr ballistocardiograph; various more or less vague statements are all that we have to go on for other techniques. In estimations by the ballistocardiograph the reliability obtained from two tests seven minutes apart on subjects well rested, so that variation of the cardiac output with the passing of time is minimised, is 0.91 (3). The data given by Starr *et al.* (6) lead to a very similar figure for the ethyl iodide method. The statement by Grollman (7) that a retest nearly always falls within 10% of the initial value indicates that a similar figure would be a reasonable approximation for the acetylene method; while the catheterization method would seem to be slightly less reliable, from the statements of Nickerson *et al.* (8) and Warren *et al.* (9).

Though this reliability is certainly high enough to make the construction of standards worth while, it is not nearly so high as for physical measurements, or indeed as for the impressionistic assessment of physique by a skilled observer. This brings us to the second point. Can a single standard be constructed which applies to all methods of measuring cardiac output, in particular to the ballistocardiogram and to the catheterization methods? He would be a bold man who asserted unequivocally that such a standard is possible and can be constructed with present data. But he would be rash, also, who maintained one method's standards have no bearing on another's; for the quantitative relations between two methods are a subject for biometrical analysis, and arguments from the superior validity of one particular method, however justified, are not relevant to this particular problem.

The published results show an astonishing agreement between the different methods under most circumstances, when due regard is paid to the relatively low reliability of each method. The point is this: method A *cannot* correlate any better with method B than it does with itself, and probably correlates with B a good deal less. When comparing methods A and B, however, it is possible by statistical means to neutralize the unreliability of the tests, and see how closely the two methods would agree if they were not subject to such troubles: to find the true correlation of the phenomena measured, were the methods of meas-

urement not fallible. This is known statistically as correcting the coefficient for attenuation, and is done simply by dividing the method A-method B correlation by the square roots of each method's reliability coefficient (10). The Starr ballistocardiograph stroke volume for 25 subjects, covering wide age and surface area ranges, correlated with the ethyl iodide stroke volume to the extent of 0.86 (6). When corrected for attenuation so as to represent the true correlation between methods when the unreliability is taken away, this figure

becomes $\frac{0.86}{\sqrt{0.91 \times 0.90}} = 0.96$. This indicates that $0.96^2 = 0.92$ or 92% of the variance of each method is due to the factor *common* to the two methods, and only 8% to factors *specific* to each method. More important is the correlation of the Starr ballistocardiograph stroke volume with the catheterization stroke volume (11). For 14 subjects, covering a wide age range, and including normal people and sick patients, the figure was 0.94. The figure is slightly inflated by the average of two ballistic records being taken, and by the inclusion of aortic cross-section in the old Starr formula. This figure, corrected for attenuation, reaches unity, and if not inflated from these causes, could scarcely be under 0.95. Lastly, the Nickerson low-frequency critically-damped ballistocardiograph gave a correlation coefficient of 0.83 with the catheterization figure for 54 observations over a wide age span of patients without heart disease. This corrected would again be of the order of 0.95, and at least with this instrument "variations in arterial pressure, heart rate and age appear to cause no significant variation in the relationship between the cardiac index as measured by the ballistic method and as determined by the catheter method" (8). Thus these methods agree well, at least for healthy persons at rest; and it is from these that we obtain normal standards and measure our degree of abnormality.

The fallacy of the present ratio standard

Two expressions have so far been proposed for cardiac output standards; the output per surface area (12) and the output per body weight (5). The implications of the use of these *ratios* as standards do not seem to have been generally realised: the subject has been discussed at length

FIG. 1. THE RELATION OF STROKE VOLUME AND BODY WEIGHT

elsewhere (1). Except in a special case, not met by cardiac output figures, the ratio standard creates of itself a tendency to say large men have small stroke volumes and small men large ones and thus leads to the situation where large and small men are reported as abnormal more readily than are the medium sized.

This comes about in the following way. Figure 1 shows the stroke volume of the heart plotted against body weight (data of Table I). The use of the ratio, per-weight, standard implies that in the normal person, the stroke volume is proportional to the weight: in fact that the expression,

$$\text{Stroke Volume} = k. \text{Wt.}, \quad (P)$$

holds good over the range of values of weight for which the standard is used: that is, for all normal adult values. The constant k is determined by the mean values of the series of data on which the standard is founded. Thus the line in

equation P passes through the point of the two means, and, by virtue of the form of the equation, through the origin also. If this line were really a newly constructed per-weight standard, we should judge any given stroke volume as normal or abnormal according to how far away from the line our value fell. This is the current practice, using either the per-weight or per-surface area standard. Now actually this expression by no means represents the mathematically "best" or "true" relation between stroke volume and weight over the range of adult values. The best relation is that given by the regression equation (assuming rectilinearity of regression, which is justified at least as a first approximation), and this equation is:

$$\text{Stroke Volume (ml.)} = .32 \text{ wt. (kg.)} + 79.5. \quad (Q)$$

This is the line called equation Q in Figure 1, and it will be seen that it only coincides with that of

equation P at one point, the means. Equation P should be our proper standard, and it can be seen from the figure that a heavy man of 90 kg. will be given by the ratio standard a "normal" stroke volume which is too high, by as much, in this instance, as 20%. At the end of this paper the example chosen to illustrate the application of the new standards also illustrates this point.

The regression equation also has the advantage that a precise test of significance of the difference between the values found and those predicted is available. That is, confidence limits can be precisely specified, such that only one normal man in 20, or one in 100, as is wished, is reported wrongly as abnormal. A similar test is not so readily available for the ratio standard.

The multiple regression equation standard in theory

Correct normal standards of cardiac output should be constructed, then, from the regression equations found experimentally in healthy people. We not only wish to have standards for every weight, but also for each age, for either sex, and indeed for the varying conditions of all the variables upon which, in the normal individual, stroke volume depends. The more precise the standard for the normal, the smaller the variation we shall be able to identify as abnormal, and the earlier the diagnosis of disorder. What we need is a multiple regression equation in which is shown the dependence of stroke volume upon many variables, each with its own effect separated off from the effects of the others. Stroke volume, we may say, is given (in the normal) by

$$V_s = aL + bM + cN + dO + eP, \quad (A)$$

where L, M, N, etc. are such variables as weight, age and sex, and a, b, c, etc. are coefficients. Such an equation assumes that the relationships between all the variables concerned are linear, though there is no reason why more complicated functions either stated curvilinearly or reduced to linearity by taking logarithms or by some other means should not be used if they represent the data better. Our present data warrant no other assumption than that of linearity, except possibly in the case of age. Multiple regression equations of this sort are used in the newer tables of children's weights, and have

been constructed by pathologists to help them identify abnormal tissues (13). A very full and exemplary treatment of their construction and use for basal metabolism standards will be found in Harris and Benedict's monograph (14).

Cardiac output per minute is a physiologically important but composite variable, and its components, stroke volume (V_s) and heart rate, are governed by factors which are to a large degree independent of each other (as signified by V_s and heart rate having a negative correlation at rest of about -0.4). Both stroke volume and heart rate are of very considerable interest in themselves, and it would therefore seem best to have standards for these two variables, as well as for cardiac output per minute. It could then immediately be seen whether a person with a high cardiac output had it because of a high heart rate for, let us say, his age and sex, or a high stroke volume for his size, age and heart rate.

The variables that enter into the multiple regression equations depend, of course, on the correlations found empirically for healthy people. But *a priori* we may surmise that we should allow for age, sex, and body size and shape. Height, weight and surface area are merely crude ways of considering physique; these relations will be discussed in more detail in the next section. Our theoretical equations may then be:

$$\begin{aligned} \text{Stroke Volume} &= a. \text{ Body Size factor} + b. \text{ Age} + c. \text{ Heart rate} + d. \text{ Chest dysplasia} + e. \text{ Androgeny of Physique} + f \dots \dots \dots (B) \\ \text{Heart Rate} &= a'. \text{ Body Size factor} + b'. \text{ Age} + c' \dots (C) \\ \text{Cardiac output/min.} &= a''. \text{ Body Size factor} + b''. \text{ Age} + c'' \dots \dots \dots (D) \end{aligned}$$

It is proposed to derive equations of this type for each sex with the accuracy the data available permits.

The data

In Table I are listed the data for 50 healthy students. These determinations were made between 12 noon and 3.30 p.m. in June with laboratory temperatures varying from 21.2° C to 33.5° C. The subjects had taken no strenuous exercise on the day of the test, and had not smoked or had anything to eat or drink for three hours previously. Each sat in a chair resting for 30 minutes and then lay down on the ballistocardiograph. At the end of 14 minutes a recording was taken, and another at the end of 21 minutes. The figures in Table I are the average of these two determinations (3).

Table II sets out the biometric relations of all available studies which give full figures, including the heights and weights of the subjects. The first and third columns refer to the data of Starr, the second to the contents of Table I. These three columns are results from Starr's high-frequency ballistocardiograph, using the area formula of Starr, omitting A, the aortic cross-section area, and using 100 instead of 33 as the constant, the reason for which is given below.

The fourth and fifth columns refer to acetylene method results. Lewis studied 100 apparently healthy middle-aged and old men (15), but only the data on the 80 subjects between the ages of 40 and 79 figure in the Table II calculations. Grollman's subjects were mostly medical students in the post-absorptive state (12). The sixth column lists data obtained by Starr and his colleagues using ethyl iodide (16), and the last two columns are from cardiac catheterization studies.

Very few catheterization data are available on normal subjects. This being the case, it is all the more unfortunate that the two available series, due to Cournand *et al.* (17) and Stead *et al.* (18), do not agree. Stead's value for stroke volume for ten normal subjects ([18] their group 1 plus WP of group 4) of mean surface area 1.93 sq.m., heart rate 70.3 and age 25, was 85.6 ml. Cournand's 13 subjects' mean stroke volume, when adjusted to Stead's means of surface area, heart rate and age, is 96.2 ml. or 96.6 ml. according to whether the adjustment is made using the regressions of Cournand's sample itself or of equation B3, below. In either case the difference between Stead's and Cournand's means is more than twice its standard error, and unlikely to be due to chance; it stems from a difference in arterio-venous oxygen difference, due to method, climate, choice of subjects, or some other factor. Thus the two series cannot be considered as from the same population and must be dealt with separately.

In the upper part of Table II means and standard deviations of the various variables are tabulated; the standard deviations are figures for the sample. The heart rates serve as a guide to the degree of rest and relaxation of the subjects; in three of the four large male series they are satisfactory, but Starr's ballistocardiograph group have rather high rates, perhaps because they were not in the post-absorptive state.

The middle part of Table II lists the regressions and partial regressions that we are concerned with, and which constitute the most important part of our analysis. These regressions are estimates of regressions in the population from which each sample was drawn, but some are, of course, much better estimates than others, due to the relative size of the samples. The standard errors are the figures in italics each below and to the right of the parent regression coefficient. The sampling error of the catheterization data in particular is distressingly large in relation to the making of standards.

The lower part of Table II lists various correlation coefficients of interest, and provides a way of judging the goodness of fit of the regression lines specified. The level of r for which $P = .05$ is given, and for coefficients

of this size the figure for twice the standard error of each coefficient will not be very much smaller than this.

In Table III are the more detailed statistics for age changes in cardiac output from the studies of Starr and of Lewis.

BALLISTOCARDIOGRAPH STANDARDS

Leaving a further consideration of Table II to the last part of the paper, we will now develop the appropriate standards for the Starr ballistocardiogram.

The revised ballistocardiogram formula

The dropping of A, the cross-sectional area of the aorta, from Starr's ballistocardiogram formula (19) leaves the value of the constant in the formula indeterminate, and before we can give regression coefficients for stroke volume we must adopt some particular figure. The value to be chosen is that which will bring the mean normal figure for stroke volume calculated from the ballistocardiogram into line with the mean obtained by the catheter technique.

Using the Starr area formula without aortic cross-section and omitting the constant 33 (*i.e.*, $V_s = \sqrt{(2I \text{ area} + J \text{ area})} \sqrt{c}$ where the areas are measured in millimeter-seconds, and 280 gm. displace the light spot 1 cm.), the mean value for Tanner's 50 men of average age 23 is 1.02 ml., and for Starr's 24 men (Table III) of average age 24 is .92 ml. When both these means are adjusted for surface area and heart rate differences by equation B3, so that they correspond to the value of a group of surface area 1.80 sq.m. and heart rate 62, Tanner's series mean is 1.00 ml. and Starr's .94 ml. The difference between the two series is just twice its standard error; probably Tanner's subjects have higher outputs because they were all measured in the summer. A figure of about .96 ml. would perhaps be the best all-the-year-round estimate. The question is whether to bring this up to Stead's mean catheter figure, or to Cournand's. I have chosen, pending more data, to bring it to the latter, chiefly because this makes the constant the convenient and self-evidently approximate figure of 100. It is recommended that this be used in Starr's area formula, until further developments take place.

TABLE III
Changes in cardiac output with age

		Starr: Ballistocardiograph							Lewis: Acetylene					
		Males					Females							
Age		20-29	30-39	40-49	50-59	60-79	20-29	30-49	50-69	40-49	50-59	60-69	70-79	80-89
Number		24	29	29	18	8	29	27	10	20	20	20	20	20
Surface Area	M	1.86	1.91	1.92	1.91	1.85	1.57	1.61	1.72	1.82	1.82	1.79	1.75	1.68
	σ	.13	.11	.14	.12		.14	.12		.14	.13	.15	.13	.15
Heart Rate	M	70.6	71.5	67.8	72.2	77.5	73.6	70.7	69.5	61.1	60.8	60.1	58.7	62.9
	σ	7.3	9.6	7.9	9.0		10.0	8.1		5.1	8.1	7.5	6.8	9.0
Stroke Volume	M	92.4	86.7	82.1	66.8	48.5	70.4	67.4	62.8	71.3	67.4	68.1	66.5	60.0
	σ	10.5	10.8	13.6	12.6		7.8	8.5		10.2	10.9	9.0	10.5	10.3
Cardiac Output	M	6.51	6.19	5.52	4.75	3.74	5.19	4.76	4.34	4.32	4.04	4.06	3.86	3.74
	σ	.88	.97	.86	.69		.85	.77		.57	.37	.48	.47	.65
I wave area	M	21.7	19.9	17.0	9.7	9.4	12.2	11.3	8.4					
	σ	6.9	5.4	7.5	4.4		2.9	3.0						
J wave area	M	50.1	42.4	39.6	30.0	24.6	32.2	27.9	25.9					
	σ	10.2	12.4	9.2	8.8		7.8	5.8						
I/J		2.3	2.1	2.3	3.1	2.6	2.6	2.5	3.1					
Average blood pressure	M	93.8	96.9	94.4	97.4	111.4	91.2	96.0	106.5	91.1	97.6	94.8	105.6	114.0
	σ	7.8	5.7	8.4	7.3		6.9	9.7		6.6	7.9	8.5	11.2	13.0

This new constant is probably too high; it assumes that persons lying at rest with an intra-cardiac catheter in place and a needle in the femoral artery are as truly basal as those lying in perfect comfort on the ballistocardiograph, and this is unlikely to be true. It places the mean level for ballistic stroke volumes considerably above that obtained by adding 18.5% to the old Starr formula, as suggested by Cournand (11), which gives a value of 60 for the constant, and leads to the rather low figure of 3.7 l/min. for the cardiac output of healthy young men at rest. (Current model experiments, Professor Starr tells me, support the figure of 60, all the same.) That at present we have no means of knowing absolute values from the ballistocardiogram is of no importance whatever so far as our standards are concerned. As used in practice they are independent of the constant and of any absolute level. When the constant changes as a result of further data accumulating, the regression coefficients in equations B3 and C3 below will change proportionately, but the standard error of estimate (see below, p. 577) will do likewise and the probability of a patient being abnormal will remain unaltered.

The relation with body size

There are two classifications of physique which command attention at the present time. One of these is due to Sheldon (4), and the other, resulting from applying the methods of factor analysis to measurement of the body, has reached its most advanced position in the hands of Burt (20). A discussion of the principles of these systems and of the relation between the two will be found elsewhere (21). The factor analysis yields a general Body Size factor, and several subsidiary factors such as the leptosomic, or linearity factor, which is the equivalent of Sheldon's ectomorphy. The Size factor is a measure of the simple largeness of the body; every measurement taken on the body correlates positively with it. It is really this Size Factor that we are attempting to consider when we regulate the dosage of a drug by body weight or calculate cardiac output per kilogram or per square meter. (We may thereafter, it is true, proceed to consider the relative amounts of more or less active tissue, the bone, muscle and fat proportions, but only *after* the general size has first been allowed for, or, in statistical language,

partialled out.) An estimate of a man's Size Factor score may be obtained from a regression equation involving height and weight and sacrum-heel length (22) and it is this Size Factor estimate which we should use as the first term in our multiple regression equation for cardiac output. However, another expression has been substituted, and this the familiar one, DuBois Surface Area (23). This surface area expression can be shown for men to correlate with the Size Factor estimate to the extent of .98 and its use therefore gives precisely the same result: it is a trifle simpler to measure and compute and is already familiar to clinicians. It should be again emphasized, however, that the surface area is used simply because it provides a good estimate of the Size Factor and for no other reason. There is no implication whatever of theoretical physiological relations concerning surface area and cardiac output, such as caused controversy in the field of basal metabolism (14, 23, 24). The figure used for weight should be the subject's usual weight in health: under no circumstances should any so-called "ideal" weights be used, which are merely methods of telling what weight a given person would have if he were somebody else of entirely different appearance. I have used surface area as equivalent to the Size Factor for women as well as men, and the propriety of doing so might well be questioned: data on the subject are lacking.

The regression of stroke volume on surface area for ballistocardiograph data can be seen in Table II. The figure for women is less than that for men, but this seems to be due to the existence of a positive relation between surface area and age in the series of women, but not in the men. Partial regressions with age constant give almost identical figures for both sexes.

Heart rate and body size seem to be independent of each other. The heart rate has insignificantly small correlations with height, weight and surface area in all the data of Table II. The large series of Boas and Goldschmidt (25) and Harris and Benedict (14) gave almost exactly zero correlations. We may conclude that resting heart rate in the human is unrelated to the Size Factor.

Beyond the general Size Factor, one may suspect that a person's *body build* may influence his cardiac output. In the 50 young men of my series, however, no sure relation could be demon-

strated between heart rate, stroke volume or cardiac output and any of the Sheldon components (3). Correlations with Burt's leptosomic factor scores (taken to increase as linearity or ectomorphy increases, contrary to the usage in my previous study [21]) were only .18 for stroke volume and .19 for cardiac output, either of which would be expected to occur once in five samplings of a population in which there was no correlation at all; and .06 for heart rate. Thus at present, though some quite small positive relation between stroke volume and linearity of build may exist, the inclusion of body build factors other than general size would not substantially improve our standards.

Stroke volume and heart rate

The relationship between stroke volume and heart rate is an inverse one. There is good agreement, particularly in the partial regression, between the two male ballistocardiograph series, but the figure for women seems only to be about half as large.

Stroke volume and age

The regressions and correlations are in Table II and some more detailed statistics in Table III. Starr's male data show a very marked decrease with age, with a linear correlation of $-.65$. The female regression is again about half the male.

The standard regression equations

We are now in a position to assign values to the coefficients in the regression equations B and D, for the ballistocardiograph. These values are the partial regressions in Table II; but they have been rounded off to avoid giving an unwarranted appearance of high accuracy. The figures for stroke volume on surface area are sufficiently close for the value 25 to be used for males and females; for stroke volume on heart rate, $-.50$ covers adequately both male series. We then have:³

$$\text{Estimate } V_s \text{ (ml.)} = 25 \text{ (S. Area} - \text{Mean S. Area)} - .50 \text{ (H. Rate} - \text{Mean H. Rate)} - .80 \text{ (Age} - \text{Mean Age)} + \text{Mean } V_s \text{Men, ballisto (B1)}$$

³ A set of somewhat different equations based on preliminary calculations has appeared in the Proc. Phila. Physiol. Society, Amer. J. M. Sc., 1948, 216, 598. The present equations replace those preliminary ones.

and

Estimate V_s (ml.) = 25 (S. Area - Mean S. Area) -
 20 (H. Rate - mean H. Rate) - .40 (Age - Mean
 Age) + Mean V_s Women, ballisto (B2)

The partial regression coefficients in the equations refer to population values, but the figures to be inserted for the means of stroke volume, surface area, heart rate and age should perhaps be taken by each separate laboratory from the usual run of its own data. In this way, though the mean stroke volume figures may differ in different laboratories due to variations in method, climate and so forth, estimates of V_s will always be couched at the same level as the actually recorded measurements. We must perforce assume that the standard deviation is unaffected by such changes in the mean as we have to deal with. For heart rate, at least, the figures of different series agree very well, both as to mean and standard deviation (3, 12, 14, 25). The population mean for resting males may be taken as approximately 62, and the standard deviation as about 8. For women these figures are 69 and 9. These values only apply if really sufficient time of resting is allowed the subject before determination; at least 15 and perhaps 20 minutes. The subject should preferably be in the post-absorptive state.

Using 100 as the constant in the ballistocardiograph equation, the mean of Starr's series is 82 ml. for men and 68 ml. for women. Putting in the means of his samples also for surface area, heart rate and age, we finally have:

Estimate V_s (ml.) = 25 S. Area - .50 H. Rate - .80 Age
 + 103 Men, ballisto (B3)
 Estimate V_s (ml.) = 25 S. Area - .20 H. Rate - .40 Age
 + 56 Women, ballisto (B4)

These equations, as has been emphasized, should be regarded only as major terms in longer, more accurate, expressions. They are inapplicable below the age of 20, and of doubtful validity above the age of 70. The standard errors of the coefficients have been indicated in Table II. The multiple correlation of V_s in these equations is .77 for men, and .50 for women; that is, surface area, heart rate and age account for 53% of the variance of stroke volume estimated by the ballistocardiograph in men, and 25% of the variance in women.

By substituting an individual's measurements in the relevant equation, we obtain an estimate

of what his stroke volume should be on the basis of his surface area, heart rate and age. We then discover experimentally his actual stroke volume. Naturally the actual stroke volume differs from the estimate by a certain amount, which we will call d . The question to which the clinician requires the answer, and to which all the above development has been leading is simply "What is the likelihood that this man's difference, d , is due merely to sampling from the normal population?". This is a more valid form of the cruder question "Is this man's stroke volume normal or not?", for if the likelihood of the man's difference having arisen just by sampling is small, the man is presumably *not* from the normal population, and is thus from another, abnormal one. It has been customary, with the ratio standard, to say that the man is abnormal if the difference between his actual value and the mean value, or standard, is 20% of the mean. This usage has little statistical foundation, and with the regression equation standard we can replace it with a more valid and more informative device. The estimates we make from the regression equation have a standard error, and a guide to the likelihood of a given man *not* coming from the normal population is directly given by the ratio of the difference, d , to this standard error. The standard error is given by

$$\sigma_{\text{est}} = \sigma_{V_s} \sqrt{1 - R^2}, \quad (L)$$

where R is the multiple correlation coefficient. Using the figures already given, we have $\sigma_{\text{est}} = 16\sqrt{1 - .53} = 11$ ml. for men and $8.6\sqrt{1 - .25} = 7.5$ ml. for women.

The interpretation of d/σ_{est} is that of the ordinary critical ratio and from it the clinician can tell how much confidence to place in the idea that the man may be abnormal. The confidence limits usually used by statisticians are ± 2 for the ratio, which would lead to five normal men in 100 being classed as abnormal. Thus we may roughly place the limits of stroke volume normality for males at ± 22 ml. from the regression estimate. (Though these limits seem reasonably appropriate, they are quite arbitrary and stricter ones may be taken if the clinician desires; for example at ± 2.5 , which would lead to wrong classification only once in 100 people.)

Heart rate. To complete equation (C) for predicting heart rate, we need only to employ the

mean figures for both sexes. The standard deviations of the distributions of heart rates in the population are known. Again, each laboratory should use its own mean values. Whether or not a given heart rate should be considered abnormal may be tested in the same way as for stroke volume.

Cardiac output. The equivalent equations for cardiac output are:

$$\begin{aligned} \text{Estimate C.O. (1/min.)} &= 1.1 (\text{S. Area} - \text{Mean S. Area}) \\ &- .05 (\text{Age} - \text{Mean Age}) + \text{Mean C.O.} \dots\dots\dots \\ &\dots\dots\dots \text{Men, ballisto (D1)} \end{aligned}$$

and

$$\begin{aligned} \text{Estimate C.O. (1/min.)} &= 1.7 (\text{S. Area} - \text{Mean S. Area}) \\ &- .04 (\text{Age} - \text{Mean Age}) + \text{Mean C.O.} \dots\dots\dots \\ &\dots\dots\dots \text{Women, ballisto (D2)} \end{aligned}$$

With the mean values of Starr's series inserted, these become:

$$\begin{aligned} \text{Estimate C.O. (1/min.)} &= 1.1 \text{ S. Area} - 0.5 \text{ Age} + 5.5\dots \\ &\dots\dots\dots \text{Men, ballisto (D3)} \end{aligned}$$

$$\begin{aligned} \text{Estimate C.O. (1/min.)} &= 1.7 \text{ S. Area} - .04 \text{ Age} + 3.5\dots \\ &\dots\dots\dots \text{Women, ballisto (D4)} \end{aligned}$$

These equations like those for stroke volume are subject to later modification of coefficients as more data accumulate, and are applicable only between the ages of 20 and 70. The multiple correlation coefficient for men is .61 and for women .54, surface area and age thus accounting for 37% of the variance of cardiac output in resting men, and 29% of the variance in women. It may be recalled that a similar equation for basal oxygen consumption yields a multiple correlation of about .85 which accounts for 73% of variance (14). Thus our standards are only about half as effective at catching the abnormals as are the B.M.R. standards. Any future cardiac output standard that does detect abnormals as efficiently as do the present B.M.R. standards will have to be very much more complicated than those developed here.

The last point may be brought home by a consideration of the interpretation of d , the difference, as before, of the actual cardiac output from the estimated. Again we have

$$\sigma_{\text{est}} = \sigma_{\text{C.O.}} \sqrt{1 - R^2}. \quad (\text{M})$$

The higher R , the smaller σ_{est} , and thus the smaller the difference, d , to place a man outside the normal limits. We have this time $\sigma_{\text{est}} = 1.1 \sqrt{1 - .37} = .87$ l. min. for men and $.84 \sqrt{1 - .29} = .71$ l. min. for women. Confidence limits would

again be ± 2 for the ratio d/σ_{est} . Thus the limits of cardiac output normality for males would be roughly at a ± 1.7 l/min. difference from the regression estimate for men, and 1.4 l/min. difference for women.

Use of the standard equations. We may conclude this section with a couple of practical examples of the use of the new standards. Subject No. 5 of the Tanner ballistocardiograph series was aged 23; his height was 176 cm., weight 77.3 kg., and Dubois surface area 1.92 sq.m. After 20 minutes lying at rest, his heart rate was 73 per min. and calculation from his ballistocardiogram impacts gave a stroke volume of 91 ml.

To answer the question whether this man is abnormal substitute his surface area, heart rate and age in equation B3 using the Starr series means. The estimated stroke volume figure for such an individual is 96 ml. The difference between the value found and that predicted is 5, and the critical ratio of this difference to its standard error is $5/11 = 0.5$. Thus there is no reason to regard this man as abnormal. The report on this man would read "actual stroke volume 91 ml., standard estimate 96 ml., critical ratio 0.5, normal." It is instructive to consider how this man would have fared by reference to the old standards. His per-surface area estimate is 106 ml. and his per-weight estimate no less than 112 ml. On the basis of the weight standard he would be judged abnormal, with a stroke volume 21% below average.

A second man, F., aged 69, of surface area 1.89 sq.m., had a heart rate of 64 and a stroke volume estimated by the ballistocardiogram of 42 ml. He complained of nothing, worked normally, and was tested merely to add to the collection of normal data. His stroke volume, however, seems small. Is it likely he is abnormal? Substitution in equation B3 gives his regression estimate as 63 ml. The difference between the values found and estimated is 21 ml. and the critical ratio is $21/11 = 1.9$, on the borders of conventional statistical significance.¹ It is therefore relatively un-

¹ This is using the hypothesis that the man is *abnormal*, i.e., has either too low or too high a stroke volume. But if the hypothesis is that his output is too *small* (probably the more important one clinically, since other factors will usually lead one to suppose abnormality of one particular sort), then the level of normality should be taken at

likely that this man has a normal heart, despite his history; and, indeed, a few years later, he became aware of having coronary disease.

The cardiac output estimates for these two men may be calculated from equation (D3) and the likelihood of their being abnormal similarly assessed; the information yielded for these two cases is the same as above.

COMPARISON OF BALLISTOCARDIOGRAPH WITH OTHER METHODS

A few of the relations between the various cardiac output methods implied by the sea of figures in Table II seem worth fishing up and examining shortly, even if their subsequent fate is to be thrown back in. Most of this discussion concerns males only.

Stroke volume and surface area

On the present data there is little reason to suppose that any significant difference in this regression exists between the ballistocardiograph, acetylene and catheterization methods. Cournaud's series had a curiously large range of surface areas, with a sample standard deviation of .17 compared to all the other samples' .13 or .14. Perhaps this was done on purpose with the idea of covering a good range of sizes in normals; it may well be responsible for tipping up the regression line if the relationship is not really quite as linear as we would like to suppose.

There is a suspicion that the ballistocardiogram area formula may lead to higher correlations with height and lower with weight than do the other methods; possibly the length of the body influences the form of the I or J waves. Starr has himself suggested that body length should be allowed for in the ballistocardiograph formula (19), and Nickerson has included it in a revised formula for use with his low frequency instrument (8). A long aorta contains a greater mass of blood than a short one, and it is conceivable also that the time between the blood hitting the arch and the bifurcation should be larger in tall men than in short ones. Calculations on my series of 50 subjects does indeed show that the J wave area has with bodily stature a specific relation of its own: a relation, that is, not shared by the I wave.

a critical ratio of 1.65 instead of 2. One then misclassifies as too low outputs of five people in 100.

Stroke volume and heart rate

There appears to be a significant difference in this regression between the acetylene and the ballistocardiograph methods. As heart rate rises, stroke volume apparently decreases nearly twice as fast by the acetylene as by the ballistocardiograph. At least part of the reason for this seems clear enough. In both acetylene studies the second samples of rebreathed air were taken 23–25 seconds after the beginning of rebreathing, and the evidence presented by Hamilton (26) that considerable recirculation has occurred during this time seems entirely convincing. The greater the heart rate, the less circulation time (27–29), the more the recirculation, and therefore the lower, apparently, the stroke volumes: part of the negative correlation in the acetylene data is artefactual. For this reason I would be inclined to place the most likely partial regression for the catheter method near to $-.5$ rather than -1.0 ; the differences in the two catheter series are presumably due mainly to sampling error.

Stroke volume and age

There are only two considerable sets of data on age changes, and unfortunately they are in complete disagreement. Starr's ballistocardiograph data show a large decrement with age, while Lewis's acetylene data have hardly any decrement at all (Table III).

The disagreement in results is probably due to both sampling bias and to the difference in method. Lewis's subjects on which the regressions are calculated covered the age range 40–79 and were selected as being healthy men free from cardiovascular as well as other symptoms. It is perhaps not unreasonable to suppose that towards the end of the age span the subjects so qualified were those who had maintained fairly high cardiac outputs. Others, who would enter into lower age group standards as perfectly normal, and who subsequently had suffered a (not unusual) decline of output might perhaps not be free of slight symptoms. In short, there may have been selection for high cardiac outputs at the upper end of the age distribution. Secondly, in the acetylene method the amount of recirculated blood may well decrease with advancing age (27, 28, 30) and if so cardiac outputs would appear to increase.

Thus a true drop would be marked by an artefactual rise.

The only catheterization figure, from Cournaud's series of 13 subjects between the ages of 21 and 52, agrees with the ballistocardiogram figure, but its standard error is so high that the agreement cannot be taken very seriously. Somewhat in agreement's favour, however, are the data from the low-frequency ballistocardiograph of Nickerson (8). The correlation of these results and catheterization was .83 (which corrected for attenuation reaches .9) and no change occurred with increasing age in the relation between the results secured by the two methods.

There is on the other hand an argument in favour of the ballistocardiograph overemphasizing the decrement with age, and doing so in a way which may prove of great value to clinicians in the future. The area under the I and J waves reflects not only the stroke volume, but also the ejection curves of the ventricles (31). If the ejection curve changes, the formula for stroke volume becomes relatively inapplicable. Though as yet there does not seem to be any direct evidence that the ejection curve *does* change with age, that it should do so would be entirely consonant with general ideas of aging, and indirect evidence may be found, perhaps, in electrocardiographic changes (32). Such a change must be of the sort which will lead to a diminution of the area under the I and J curves, even when the actual stroke volume remains constant. It must not, however, alter the ratio of the J area to the I area, since this remains more or less unchanged as age advances (Table III). To satisfy these requirements the nature of the change can be predicted on the basis of Hamilton's curves (31, Figure 8) to consist of a ventricular contraction of usual initial speed and force but less sustained than normal; and this seems not an unreasonable thing to occur with myocardial aging.

Probably the true partial regression of stroke volume on age lies between .6 and .8 ml. per year, over the age range considered. This assumes a linear decrease of stroke volume with age, which, though unlikely to be actually true, is the only assumption warranted by the extant data. It also implies the conclusion that the arteriovenous oxygen difference rises with age,

since the oxygen consumption correlation is only about $-.3$ (33) compared to the stroke volume figure of between $-.5$ and $-.65$. Pending further developments, it would be best to use the same regression for cardiac catheter method standards, if these are needed, as for the ballistocardiogram, remembering this may exaggerate the age effect slightly. There is great need for simultaneous studies by the ballistocardiograph and catheterization methods upon normal subjects of different ages. When the position is clarified, it may well be that one of the chief clinical values of the ballistocardiogram will lie in measuring not stroke volume, but myocardial changes and efficiency.

Cardiac output and sex

The only extensive data on the cardiac output of normal women are those of Starr. When the stroke volume of the 20–29 year old women is adjusted by means of equation B4 to the same surface area and heart rate as Starr's 20–29 year old males, it is smaller than the male figure in the ratio .85. The corresponding ratio for the 30–49 year old women is .89.

The resting heart rate of women, on the other hand, is about 10% higher than that of men (14, 25), and since heart rate is not related to body size, this is irrespective of size. Thus the cardiac output per minute would be more nearly the same than is stroke volume. The ratios for Starr's groups are smaller than would be expected, probably because the subjects have greater than basal heart rates; they are .87 and .91 for the two age groups.

Heart rate and stroke volume seem to be more independent in women than in men, but this result should be treated with reserve, as the difference between the two regressions lies only at the level of $P = .075$ even if the comparison is made with both Starr and Tanner male data. Stroke volume in women apparently declines somewhat less rapidly with age than in men, and in this case the probability of the regression difference having arisen by chance sampling is only 1 in 70 ($P = .014$). The equivalent partial regressions of cardiac output on age, however, are not significantly different.

Standards for catheterization data

The data are too meagre and in too little agreement to warrant the creation at present of special catheter standards. It is recommended that the ballistocardiograph standards be used with catheter data pending further developments, and with full realization of the possible errors incurred. The fact that in some disorders the ballistocardiograph may give results widely different from the catheter, due to changes in the cardiac ejection curve, is irrelevant so far as the use of normal standards is concerned: under such circumstances the ballistocardiograph standards would relate better to the catheter results than to the ballistic ones. With the latter, one can imagine a situation where a true increase in stroke volume may be accompanied by a weakened ejection, one fault compensating for the other. Ultimately standards for the ejection curves themselves will have to be made.

SUMMARY

1. Ballistocardiographic cardiac output data, blood pressure, mouth temperature and somatotype are reported for 50 healthy young men at rest.

2. The reliability of cardiac output methods is discussed, and it is shown that agreement between the ballistocardiograph and catheterization methods is very good, if their respective reliabilities are taken account of.

3. The present use of ratio standards such as per-weight and per-surface area involves a fallacy and leads to erroneous results, sometimes of practical importance; this is discussed.

4. The construction of normal standards for cardiac output by means of multiple regression equations is discussed and the appropriate standards derived for the Starr ballistocardiograph stroke volume and cardiac output for men and women. Their clinical use is illustrated.

5. To bring the Starr ballistocardiograph data into line with Cournand's catheterization values, it is recommended that, when aortic cross-section is dropped from the Starr wave area formula for stroke volume, the constant 33 be provisionally replaced by 100.

ACKNOWLEDGMENTS

I wish most gratefully to express to Professor Starr my appreciation of his untiring advice and help, and my thanks for the use of unpublished records; the personal data quoted in this paper were obtained while I was working in his laboratory. At the time I was supported as a wartime Rockefeller student and I wish to thank these authorities for providing me, and many others, with opportunities of very great value. I wish also to thank Professor Sir Cyril Burt for the most prompt cooperation and advice he gave during the later stages of this work.

AN EVALUATION OF HUMAN SERUM ALBUMIN IN THE TREATMENT OF CIRRHOSIS OF THE LIVER^{1, 2}

By WILLIAM W. FALLOON,³ RICHARD D. ECKHARDT,⁴ T. LYNCH MURPHY,
ARNOLD M. COOPER, AND CHARLES S. DAVIDSON

(From the Thorndike Memorial Laboratory, Second and Fourth Medical Services [Harvard], Boston City Hospital, and the Department of Medicine, Harvard Medical School, Boston)

(Received for publication August 30, 1948)

INTRODUCTION

The recent development of normal human serum albumin for intravenous administration has led to its use in treating clinical states marked by hypoalbuminemia, including chronic liver disease (1-4). Previous work with this therapeutic agent has been confined to relatively short-term studies. The present study was undertaken to determine the effect of salt-poor human serum albumin on ascites and edema in chronic liver disease when administered in sufficient amounts to raise the serum albumin concentration and maintain it at or near normal over long periods of time. The results of such therapy attempted in 29 patients with cirrhosis of the liver are presented in this communication.

METHODS

Patients were selected who had marked evidence of hepatic cirrhosis by history, physical examination, and liver function tests, and who had ascites, edema, and hypoalbuminemia. In a few patients the diagnosis was confirmed by liver biopsy or at post-mortem examination. In most instances patients were chosen in whom there was no response to other forms of therapy. In the majority of cases, the need for repeated paracenteses was established before treatment was initiated. During the period of study no other therapeutic agents were given

except for a nutritious diet which the patients were urged to eat. A few patients were given mercurial diuretics at infrequent intervals but with only a temporary effect on the course of their fluid retention. The salt-poor concentrated (25 per cent) human serum albumin was given intravenously, diluted with an equal volume of 5 or 10 per cent dextrose solution. Quantities of albumin necessary to raise the serum albumin concentration to between 3 and 4 grams per 100 cc. varied: usually from 50 to 100 grams daily were given over a five to ten day period. The majority of patients received 75 grams per injection and thereafter 75 grams once, 50 grams twice or 25 grams three times weekly. If marked improvement in ascites was not observed during the first ten days of treatment, maintenance injections were continued for from three weeks to eight months. In three patients the effect of a low sodium diet was studied during albumin therapy.

Abdominal paracentesis was performed as necessary and whenever possible the protein concentration was determined on the fluid obtained. The serum protein concentration and albumin and globulin fractions were determined at weekly intervals; total protein by micro-Kjeldahl analysis and albumin and globulin separation by Howe precipitation (5). Serum thymol turbidity (6) and serum bilirubin (7) were determined at weekly intervals. The percentage of bromsulphalein retention, 45 minutes following a 5 mgm. per kilogram dose, was determined at less frequent intervals. Most of the patients were weighed daily and frequent abdominal girth measurements were made. The latter were found to correlate well with weight gain and ascites formation.

RESULTS

Twenty-nine patients received albumin in varying amounts during periods of from four days' to eight months' duration. Table I shows the statistical results of the series. Twenty-five patients had both edema and ascites before therapy was begun and the remaining four had ascites alone. A history of heavy intake of alcoholic beverages was obtained in 25 cases, two admitted only a moderate alcoholic intake, while two denied drinking. In nine cases albumin administration had to be stopped because of untoward reactions, lack of cooperation, or untimely demise. Therefore, of

¹ The serum albumin used in this study was processed by the American National Red Cross from blood which it collected from voluntary donors. This is one of a series of investigations on serum albumin being carried out with material supplied by the American National Red Cross. As soon as sufficient data become available to justify final conclusions concerning its therapeutic value a full report to the medical profession on the use of serum albumin in medical practice will be published.

² This study was aided in part by a gift to Harvard University from the Abbott Laboratories, North Chicago, Illinois.

TABLE I
Results of albumin administration to patients with cirrhosis of the liver

Patient	Total albumin given grams	Period of therapy	Paracenteses necessary*			Period of follow-up since therapy and end result
			Before therapy	During therapy	After therapy	
Immediate improvement						
S. P.	450	6 days	0	0	0	Free of ascites—11 months.
F. F.	375	5 days	0	0	0	Free of ascites—5 months.
S. H.	300	6 days	0	0	0	Died of bleeding varices 1 week after treatment.
J. G.	400	4 days	0	0	0	Recurrence of edema and ascites after 6 weeks. Died in coma 4 months later.
Slow improvement						
G. D.	1000	3 months	2(16)	0	0	Free of ascites—16 months.
P. B.	675	5 weeks	1	0	0	Free of ascites—10 months.
J. M.	1075	7 weeks	3(17)	1	0	Moderate ascites not requiring tap—8 months.†
A. D.	1500	6 weeks	1	0	0	Recurrence of edema after 6 weeks. Free of ascites—11 months.
H. H.	600	8 days	3(6)	0	—	Recurrence of edema and ascites after 6 weeks. Refractory to retreatment. Died of bleeding varices during therapy.†
Delayed improvement						
J. S.	1975	6 months	6(15)	4(24)	0	Free of ascites—6 months.
W. M.	3675	7½ months	4(23)	6(29)	0	Free of ascites—8 months.†
Improvement only with low sodium diet						
E. G.	2405	6 months	2(28)	3(33)	1	Died in coma 2 months later.
V. L.	1825	2 months	2(14)	1	—	Died of bleeding varices during therapy.
C. M.	4000	7 months	2(15)	9(28)	—	Still reforming ascites—under treatment.
Failure						
M. C.	1750	3 months	2(30)	7(15)	4(19)	Ascites increased with therapy. Died in coma 3 months later.
F. G.	350	5 days	3(30)	0	0	No apparent early benefit. Died in coma 2½ months later.
H. G.	900	3 weeks	4(34)	1	—	No apparent benefit. Died of bleeding varices 6 weeks later.
N. C.	900	3 weeks	3(16)	2(7)	—	Died in coma during therapy.
R. A.	525	18 days	1	1	—	Died of epistaxis 48 hours after last albumin.
P. W.	2300	4½ months	1	6(20)	—	Died in coma during therapy.
Indeterminate						
C. F.	425	12 days	3(33)	1	—	Pyrogenic reaction—coma. Died in coma 8 days later.
J. C.	450	7 days	1	0	—	Died during treatment from diphtheria infection of abdominal skin.
H. K.	450	9 days	2(15)	0	—	Pleural fluid increased with therapy. Left against advice—no follow-up.
R. V.	400	26 days	0	0	0	Intestinal obstruction during therapy. Died of int. obs. 2 months later.
B. B.	375	5 days	0	0	0	Improvement possibly spontaneous. Free of ascites—9 months.
L. B.	150	2 days	4(30)	0	0	Pulmonary edema with therapy. Spontaneous diuresis. Free of ascites—7 months.
J. Q.	225	6 days	0	0	0	Diuresis before therapy begun. Died in coma 2 weeks later.
P. M.	150	2 days	0	0	—	Pulmonary edema with therapy. Died in cardiac failure 1 day later.
F. H.	300	12 days	0	0	0	Improvement possibly spontaneous. Free of ascites—2 months.

* Average interval (days) between paracenteses given in parenthesis.

† Sodium balance studies were done on these patients who received a low sodium diet for short periods of time.

the total number, 20 patients are considered to have had sufficient therapy and follow-up to determine the effect of treatment. Improvement was judged on the basis of diminution in ascites and edema and other signs of improvement clinically and by laboratory tests. There was often a discrepancy between the decrease in fluid retention and improvement in other manifestations of liver disease. In this study the change in ascites and edema was used as the prime criterion of improvement.

The results presented in Table I can be divided into four main types: (1) immediate improvement with diuresis seen within the first ten days of treatment; (2) slow improvement with fluid retention disappearing (diuresis taking place) during one to three months of therapy; (3) delayed improvement with relief of ascites and edema occurring over six and eight month periods; and (4) failure to improve. Three patients were treated with a low sodium diet in conjunction with the albumin and are therefore classed separately.

Prompt diuresis occurred in four patients with complete relief of ascites and edema (Table I). This took place during or immediately following the administration of from 300 to 450 grams of albumin. Weight loss began in each instance before a sustained rise in serum albumin concentration was detected. The course of one patient typical of the group is shown in Figure 1. It can be seen that weight loss began in this patient before the serum albumin concentration rose above

Fig. 1

Fig. 2

3.0 grams per 100 cc. Edema and ascites recurred in one patient with this type of response six weeks after therapy was stopped. Improvement was apparently permanent in two others who have been followed for five and 11 months, respectively. The fourth patient had a fatal hemorrhage from esophageal varices one week after the last administration of albumin.

Definite improvement at a slower rate was seen in five patients after therapy had been continued for from eight days to three months (Table I). The response shown by this group is typified by the findings in one patient (G. D.) shown in Figure 2. Of these five patients, recurrence of ascites and edema took place in one (H. H.) approximately six weeks after the last injection of albumin. This patient was subsequently refractory to retreatment and died of hemorrhage from esophageal varices during therapy approximately five months after the initial albumin was given. A second patient (A. D.), although free of ascites for 11 months, noted a recurrence of peripheral edema six weeks after the cessation of albumin. Varicose veins in both lower extremities undoubtedly contribute to the edema in this patient. The improvement of the remaining three is maintained at eight, 10, and 16 months' follow-up examinations.

The two patients in whom disappearance of ascites and edema occurred only after prolonged treatment received albumin injections over periods of six and eight months, respectively (Table I). At the end of this time each had stopped reforming ascites in spite of having required numerous paracenteses before and during treatment.

FIG. 3

One of these patients, J. S., seen six months after therapy was discontinued, showed no ascites in spite of the resumption of a large intake of alcohol, and the second has been seen eight months after cessation of albumin therapy, still free of ascites. The hospital course of the first of these is shown in Figure 3. It may be seen that electrophoretic analysis⁵ of the serum albumin concentration was generally lower than that determined by the Howe separation. Thus, the level at which the serum albumin was actually maintained was considerably lower than was supposed. Moreover, reaccumulation of fluid ceased coincident with a rise in serum albumin concentration (electrophoretic analysis) which was not associated with an increase in albumin administered. Whether this rise resulted from cessation of ascites formation and removal, or from increased production of albumin by the liver, cannot be ascertained from these data. The ineffectiveness of albumin in the amount administered is demonstrated.

Because of rapidly reforming ascites in spite of albumin administration, three patients were treated with low sodium diets⁶ while receiving maintenance injections of albumin (Table I). One of these was well controlled without paracentesis for two months while previously he had required paracentesis at two-week intervals. At the end of this period, five days after the last albumin administration, he bled from esophageal varices and

⁵ Per cent of the total serum protein (Kjeldahl) appearing as albumin in the Tiselius pattern. The authors express their appreciation to Dr. Frank H. Clarke, Lederle Laboratories Division, American Cyanamid Company, Pearl River, New York, for these determinations.

⁶ The low sodium diet provided approximately 100 grams protein and 3,000 calories but only 21 mEq. Na (12 grams NaCl) daily.

expired. A second patient was followed for eight months, during which time only one paracentesis, three months after the diet was begun, was required. Previous to the low sodium regimen, in spite of albumin therapy, paracentesis had been necessary twice a month. Figure 4 shows part of the course of the latter patient. The third patient, now under treatment for seven months, continues to reform ascites but at a considerably reduced rate while receiving a diet restricted in sodium. The importance of sodium in cirrhosis has been the subject of a separate investigation (8).

Despite continued therapy with albumin for from five days to four months, six of the 20 patients in whom the effect of albumin could be evaluated must be considered failures. During the period of treatment the attainment of significantly increased serum albumin concentrations did not improve ascites although edema of the lower extremities was decreased. The end results and reasons for cessation of therapy in this group of failures are shown in Table I. Reformation of ascites was accentuated in one patient by albumin administration, as shown in Figure 5. None of this group is still living.

An indeterminate group also included in Table I has been so classified because treatment could not be continued or the follow-up was insufficient to enable judgment of the result. None of these patients is now receiving albumin. Two may be considered to have received some benefit but other factors cannot be definitely ruled out. One patient, B. B., began to form ascites while recovering from jaundice after a prolonged bout of drinking. During the five-day period when albumin was given, weight loss occurred but this may have been

FIG. 4

FIG. 5

spontaneous. The second, F. H., was a patient with known esophageal varices for which a spleno-renal anastomosis had been done. Post-operatively, ascites formation became apparent and albumin was therefore administered. Weight loss and disappearance of the peritoneal fluid took place but the factor of diminished portal pressure following the shunt procedure may have been operative in this case.

Untoward effects of albumin administration

The intravenous administration of concentrated albumin as a therapeutic agent in cases of hypoproteinemia has been accompanied by certain untoward reactions which should be emphasized. In this series of 29 cases, reactions which albumin may have precipitated were seen in ten. As mentioned above, fatal hemorrhage from esophageal varices occurred in three patients during the period of albumin therapy. One occurred one week after the last previous albumin infusion, one five days after, and the third patient had hematemesis six hours after an infusion which was pyrogenic. Although in cirrhosis with varices hemorrhage may occur at any time, albumin may have been a precipitating factor by increasing the plasma volume (9).

Hematemesis occurred in one patient after albumin administration, with recovery. Subsequently, a duodenal ulcer was demonstrated as the probable source of the bleeding. In a patient with frequent epistaxis prior to treatment, fatal hemorrhage from the nose took place after he had received 525 grams of albumin over an 18-day period. Such incidents as these two must also be considered possible sequelae of albumin therapy.

One patient (P. M.) with a previous history of cardiac failure during an attack of acute glomerulonephritis developed pulmonary edema during

the second daily infusion of 75 grams of albumin, although he showed no physical signs of cardiac disease at the beginning of treatment. He died in cardiac failure 12 hours thereafter. A 65-year-old female also developed pulmonary edema during the second day of albumin therapy (75 grams daily); albumin was discontinued and she recovered. Two patients, both elderly women, developed pleural effusion while receiving albumin and required thoracenteses. In the first (H. K.), severe dyspnea was noted after one week's administration and treatment was discontinued, while the second (E. G.) showed slowly progressive dyspnea in spite of the maintenance of a low sodium intake. Cessation of albumin therapy resulted in control of pleural fluid formation. With the exception of the first of these patients, P. M., no history or sign of cardiac disease had been noted prior to treatment and cessation of therapy was not followed by residual signs of heart disease. However, the dyspnea seen in patients H. K. and E. G. was due to the pleural effusion and probably was not of cardiac origin.

Pyrogenic reactions following albumin administration have been rare, and in no case has the albumin supplied been directly implicated. However, the dangers of such pyrogenic reactions in advanced cirrhosis are amply illustrated by the one fatality occurring under these circumstances. C. F., a 56-year-old female, received albumin for 12 days with what appeared to be a good response. On the 12th day she was given 50 grams of albumin mixed with liver extract and glucose solution. A severe chill and fever followed and hepatic coma ensued from which she did not recover. No instances of homologous serum hepatitis were observed following the intravenous administration of human serum albumin in this study.

Factors influencing the retention of albumin

In attempting to determine which patients with cirrhosis will show a diuresis following albumin, the number of paracenteses necessary, the effect of entry of albumin into the ascitic fluid, and the amounts of protein lost in ascitic fluid when paracentesis is necessary have been analyzed for the patients in this series. In addition, a study was carried out of the efficacy of a low sodium diet in reducing the transfer of albumin into ascitic fluid, and subsequent loss by paracentesis.

The relationship between the number of paracenteses necessary before albumin therapy and the response obtained after treatment is shown in Table I. As can be seen, the patients who had not yet reached the stage where paracentesis was absolutely necessary had an immediate diuresis when given albumin. In these subjects, the edema of lower extremities, penis and scrotum was massive while the ascitic fluid collection was not usually severely distressing. Comparing the groups who responded to therapy with those showing no response, only seven of the 11 patients who were improved had previously required one or more paracenteses while all of the patients who required the use of a low sodium diet or who failed to improve had had paracentesis prior to treatment. If, as is generally accepted, the necessity for abdom-

inal fluid removal is an indication of the severity of liver disease, then it is apparent that those patients whose disease is more severe have the poorest therapeutic result when albumin is given.

Mankin has shown that the osmotic pressure changes of ascitic fluid and serum parallel each other under varying conditions in patients with liver disease and ascites (10). The protein values of serum and ascitic fluid obtained from 15 patients in this series, before and during albumin therapy are listed in Table II. The total protein concentration in the ascitic fluid rose in all patients as albumin was administered intravenously. Moreover, this occurred in patients F. F. and J. G., both of whom had a prompt diuresis with disappearance of ascites and edema. The protein content of edema fluid (obtained by Southey tubes)

TABLE II

from these two patients and from a third, S. P., also rose during treatment (Table III, Figure 6).⁷ It is apparent that the entry of protein into the ascitic fluid occurred regardless of the final result and that a rise in protein content of edema fluid did not interfere with its reabsorption.

The entry of protein into the ascitic fluid is a source of protein loss in patients with cirrhosis because of repeated removal by paracentesis.⁸ The

total protein lost in ascitic fluid removed was compared in five patients with the total amount of albumin administered since the previous paracentesis. The results of this "balance" between parenteral protein administered and ascitic fluid protein removed are shown in Table IV. While it is realized that this is but a rough estimate and is subject to many variables, it may be seen that the total loss of protein by entry into the ascitic

⁷ A variable and undetermined portion of the increase in concentration of protein in the edema fluid and ascitic fluid of patients undergoing rapid diuresis may result from more prompt reabsorption and mobilization of the water and electrolytes than of the protein. It is impossible to ascertain, therefore, to what extent the intravenously administered albumin contributed to the final concentration by its entry into these fluids.

⁸ Albumin administered intravenously does not usually appear in the urine as whole protein. Although a large portion of injected albumin may be excreted into the urine of patients with preexisting renal disease, only a negligible amount escapes through the normal kidney even after several days of repeated daily infusions. Determinations for protein were made in the urine of several of the patients in this study. A total proteinuria of 5 to 10 grams was occasionally noted during the initial period when approximately 500 grams of albumin were administered within a week to raise the serum albumin concentration to normal, but was not subsequently observed while maintenance injections of approximately 75 grams weekly were required to maintain the serum albumin concentration. Thus, the loss of albumin into the urine of the patients reported in this study did not constitute a significant loss of administered protein.

fluid during albumin therapy is large and may even surpass the amount of protein given intravenously as albumin.

The formation of ascites was not improved in three patients in this series by the intravenous administration of albumin until a low sodium diet was simultaneously provided (Table I). It was observed that reducing the sodium intake slowed the formation of ascites, prolonged the period between paracenteses, and thus diminished protein loss. Table V shows the findings in two of the patients given albumin to maintain normal serum albumin concentrations. Ascitic fluid was collected when paracentesis became necessary, both after a period of high salt intake and again after a period of low salt intake. Although the protein loss in ascitic fluid was not markedly changed in quantity at any one paracentesis, it is apparent that the period between paracenteses was prolonged by the low sodium diet and that less albumin per day was required to maintain the serum albumin at normal concentrations during the low sodium period.

Changes in liver function tests following albumin administration

The effect of albumin administration on three liver function tests is shown in Table VI. Serum bilirubin and thymol turbidity were determined at regular intervals whereas bromsulphalein retention was done less frequently. The results were extremely variable and no consistent picture was shown. It has been demonstrated (11, 12) that

serum albumin will alter the thymol turbidity. Therefore, the apparent improvement in this test shown by some patients is not reliable nor indicative of the true state of liver function. There was a tendency, however, for the serum bilirubin concentration to decrease in those patients who had a prompt diuresis with loss of ascites and edema. It can also be seen that some patients with nearly normal bilirubin before treatment did not show improvement in fluid retention. In the patients on whom bromsulphalein tests were done before and after treatment no significant change appeared even though loss of edema and ascites was effected by treatment in some.

DISCUSSION

The use of concentrated albumin in the treatment of edema and ascites associated with hypoal-

buminemia has been viewed with optimism on theoretical grounds. Encouraging results were obtained by Kunkel (3) early in the study of its use in cirrhosis of the liver but the results of Thorn *et al.* (2), and Patek *et al.* (13) have borne out the original conservative estimate of its value made by Janeway and his co-workers (1). The series reported here reveals that a wide range of results may be obtained even when patients are treated over long periods of time. Although striking improvement was seen in a few patients, the relatively poor effect in 11 out of 20 patients studied (not including nine patients in whom the effect of albumin could not be satisfactorily evaluated) leads to a similar conservative estimate of the efficacy of albumin therapy in chronic liver disease. The fact that some patients in our series improved after the prolonged administration of

albumin suggests that such improvement may have been the result of dietary treatment alone. Furthermore, since it has been shown that albumin administered intravenously can be utilized as a protein nutrient (14), some benefit was undoubtedly derived from this nutrient effect of albumin. However, albumin is neither a specific for the treatment of the fluid retention nor the underlying liver disease.

The most economical use of albumin is obtained when the diet is low in sodium, since the formation of ascitic fluid and loss of protein is greatly reduced by this means. This is in disagreement with Armstrong (15) who has minimized the importance of a low sodium intake in the treatment of liver disease. As the data presented here indicate, the removal of ascitic fluid containing 300 grams of protein may involve the waste of between 100 and 200 grams of albumin. A high intake of salt and water increases the formation of ascites. If ascitic fluid is present in large quantities or is rapidly forming, the entry of albumin into the fluid drains protein from the serum in larger quantities than would be the case were ascitic fluid present in small quantities or its formation diminished by measures such as sodium restriction. Furthermore, to maintain a given serum albumin concentration, less albumin is required when its loss into ascitic fluid is minimized by reducing the rate of formation of ascites. A low sodium diet is of most benefit to those patients who require repeated paracenteses. However, when albumin therapy is being initiated in a case of anasarca, a diet low in sodium should yield the most efficient use of albumin, regardless of the final response.

The mechanism by which concentrated albumin induces a diuresis is not clear. Albumin administration undoubtedly increases the serum osmotic pressure. Evidence suggesting that this is an important factor is the observation of Thorn *et al.* (2) and substantiated here, that peripheral edema is most easily mobilized when therapy is begun. The importance of the osmotic factor is minimized, however, by the finding of increased concentrations of protein in the edema and ascitic fluid when albumin is given intravenously. The increase in ascitic fluid protein thus produced would appear to emphasize the importance of portal hypertension as a causative factor in ascites formation. It should be pointed out, however, that the passage of pro-

tein into ascitic fluid following intravenous albumin took place even in patients undergoing a rapid diuresis. It seems likely that factors in addition to lowered serum osmotic pressure and portal hypertension are operative in the retention of fluid in cirrhosis of the liver. Patek has shown in a limited series of studies that there is increased renal blood flow and glomerular filtration when albumin is administered (13), presumably resulting from the increased plasma volume. This may hasten salt and water excretion by the kidney. Further studies of renal function in cirrhosis both before and during albumin therapy are clearly indicated.

The occurrence of harmful effects from albumin therapy must be emphasized. Since a majority of patients with cirrhosis are over the age of 45, and are therefore subject to possible degenerative heart disease, it may be expected that a rapid increase in plasma volume such as is produced by albumin may result in cardiac complications.

Finally, the augmented plasma volume following albumin administration may increase the burden upon esophageal varices and precipitate rupture and hemorrhage. Such an occurrence may have been the cause of death in three patients in this series. In view of such incidents albumin should be administered cautiously and heroic efforts to raise serum albumin levels above normal are to be avoided.

SUMMARY AND CONCLUSIONS

1. Concentrated salt-poor human serum albumin was administered intravenously to 29 patients with cirrhosis of the liver who had fluid retention. The albumin was administered over periods varying from four days to eight months. The data were considered suitable for analysis in 20 of the patients. Of these, four patients had an immediate diuresis with loss of ascites and edema, five had a slow response in from one to three months, and two recovered from ascites and edema after prolonged treatment of six and eight months, respectively. Nine patients must be considered failures although the fluid retention was partially controlled in three by the use of a low sodium diet. The four patients who underwent immediate improvement had not required paracentesis before albumin therapy and had massive edema. Diuresis might have occurred subsequently in these pa-

tients from a nutritious diet alone. Nevertheless, albumin administration was effective by inducing an immediate, rapid diuresis, beginning before the serum albumin concentration reached normal. The slow response in seven patients cannot be definitely attributed to the albumin administered as the other therapeutic measures used concomitantly might have given as satisfactory results.

2. Fatal hemorrhage from esophageal varices was coincident with, or shortly followed, albumin administration in three patients. Severe epistaxis and bleeding from a duodenal ulcer may have been induced by this therapeutic measure. Pulmonary edema and pleural effusions were observed as untoward effects, presumably attributable to albumin therapy. The use of this form of therapy, especially in elderly or cardiac patients, or in the presence of known esophageal varices, is dangerous and caution should be exercised.

3. Albumin entered the ascitic and edema fluid following its intravenous infusion whether diuresis occurred or not. The total protein content of the ascitic fluid rose in approximately parallel fashion with the rise in serum albumin. During a given period between paracenteses in five patients the protein lost in the ascitic fluid approximated the amount of albumin administered intravenously.

4. Ascitic fluid formation was found to be retarded by a low sodium diet in three patients, and thus the loss of albumin by paracentesis was reduced. Sodium restriction allowed the maintenance of normal serum albumin concentrations more economically than did a diet unrestricted in sodium.

5. Serial serum bilirubin, thymol turbidity and bromsulphalein tests showed no consistent change during or after treatment with albumin. Recovery from ascites and edema was seen to precede the return of liver function tests to normal values.

6. It is concluded that concentrated salt-poor human serum albumin, under the conditions of this study, is neither specific for the relief of ascites nor markedly beneficial in the treatment of the underlying liver disease. In view of the variety of results obtained with concentrated human serum albumin in patients with cirrhosis of the liver, it is concluded that other factors in addition to a reduced serum osmotic pressure, as

represented by decreased serum albumin concentrations, are active in the retention of fluid.

The authors wish to thank Alice N. Ballou, Catherine M. Murphy, and Ellen V. Cobino for their technical assistance.

THE EFFECT OF HUMAN SERUM ALBUMIN, MERCURIAL DIURETICS, AND A LOW SODIUM DIET ON SODIUM EXCRETION IN PATIENTS WITH CIRRHOSIS OF THE LIVER^{1, 2, 3}

By WILLIAM W. FALON,⁴ RICHARD D. ECKHARDT,⁵ ARNOLD M. COOPER,
AND CHARLES S. DAVIDSON

(From the Thorndike Memorial Laboratory, Second and Fourth Medical Services [Harvard],
Boston City Hospital, and the Department of Medicine, Harvard Medical School, Boston)

(Received for publication August 30, 1948)

The relative importance of the serum albumin concentration, portal hypertension, and antidiuretic substances in the formation of ascites and edema in patients with cirrhosis of the liver has not been clarified. There is evidence, however, that each of these factors is important (1-3).

In an effort to eliminate the factor of hypoalbuminemia, salt-poor concentrated human serum albumin has been given intravenously. Although the serum albumin concentration may by this means be raised to normal, the edema and ascites have not been consistently relieved (4-7). Moreover, improvement in ascites and edema is observed in some instances with mercurial diuretics or simply by furnishing a nutritious diet alone (8, 9). In an attempt to find an abnormality common to these patients and consistently altered by the apparently unrelated therapeutic agents, the studies of sodium excretion and balance reported here were undertaken.

METHODS

The 11 patients studied had ascites and edema associated with cirrhosis of the liver, established by history,

¹ A preliminary report of this investigation was presented before the national meeting of the American Federation for Clinical Research, Atlantic City, N. J., May 4, 1948 (*Am. J. Med.*, 1948, 5, 623).

² The serum albumin used in this study was processed by the American National Red Cross from blood which it collected from voluntary donors. This is one of a series of investigations on serum albumin being carried out with material supplied by the American National Red Cross. As soon as sufficient data become available to justify final conclusions concerning its therapeutic value a full report to the medical profession on the use of serum albumin in medical practice will be published.

³ This study was aided in part by a gift to Harvard University from the Abbott Laboratories, North Chicago, Illinois.

⁴ Present address: Albany Hospital, Albany 1, New York.

⁵ U. S. Public Health Service Postdoctorate Research Fellow.

physical examination, liver function tests, and occasionally by needle biopsy. Six patients had had a previous trial with intravenous albumin when the diet was unrestricted in sodium without marked response (patients V. L., W. M., C. M., H. H., A. McM., and J. McC.). The others were observed for two or more weeks on an unrestricted diet and no tendency for spontaneous improvement had been shown at the time studies were begun. None of the patients showed evidence of co-existing cardiac or renal disease.

With the exception of experiment No. II (S. P.), a low sodium diet was used. To increase the protein and caloric content of the diet, 150 grams of salt-poor milk powder containing 45 grams of protein mixed with water were used in place of milk.⁶ By calculation,⁷ the diet contained 100 grams of protein, 3,000 calories, and only 21 mEq. (0.5 grams) of sodium daily, and was well tolerated by the subjects. The sodium contained in the albumin solution⁸ was added to the sodium intake. Patients who received added sodium were given weighed amounts of salt and were either instructed to use it daily on their food or it was mixed in food and fluids consumed.

All patients were carefully followed on the Thorndike metabolic ward, with nurses and a dietitian in constant attendance. Strict control of each patient's dietary intake and urinary output was maintained throughout the study. All patients were allowed to drink water freely, and the daily fluid (liquid) intake was recorded. Fluid balance measurements obtained by differences between the fluid intake (liquids plus estimated fluid ingested in the diet) and fluid output (urine plus estimated fluid lost via the

⁶ "Lonalac," supplied by Mead Johnson and Company, Evansville, Indiana. Each 150 grams of powder contains approximately 0.7 mEq. (15 mgm.) of sodium.

⁷ It has been pointed out (10) that diets analyzed for sodium usually contain more than the amount calculated. This, in addition to the fact that strict control over the use of canned foods was not always possible, constitutes probable sources of error in our calculation of sodium balances. As will be seen, however, these factors merely accentuate the retention of sodium shown in these patients. Thus, when sodium equilibrium is shown, there is probably in reality a slight positive sodium balance.

⁸ The sodium contents of the lots of albumin used were obtained through the courtesy of Dr. Charles A. Janeway, Children's Hospital, Boston. Each 25 grams of albumin contains approximately 15 mEq. (0.3 gram) of sodium.

stools, lungs, and skin) are variable and unreliable. Since all patients in this study were weighed daily under similar conditions, it was considered that changes in body weight reflected more accurately changes in fluid retention in the body than did the difference between the fluid intake and the urine output.

Urine sodium excretion was determined daily except for a few studies in which the urine was analyzed in three- or four-day pools. The method of Consolazio and Dill was used (11). The extrarenal sodium loss was estimated to be constant at 20 mEq. per day (12-14). The studies were carried out during the winter months so that perspiration was minimal.

Concentrated salt-poor human serum albumin (25 per cent solution) was given in amounts of from 25 to 75 grams (100-300 cc.) in each injection with equal volumes of 5 or 10 per cent dextrose in distilled water. When maintenance of the serum albumin concentration was desired, 25 grams of albumin were administered daily, or three times weekly. The serum albumin concentration was determined by micro-Kjeldahl analysis of fractions separated by the method of Howe (15).

RESULTS

I. The effect on ascites and edema of varying the salt intake while maintaining a normal serum albumin concentration (Table I, Figures 1-5)

Four patients (W. M., C. M., H. H., and V. L.) who had previously had numerous abdominal

FIG. 1

paracenteses with regular reaccumulation of fluid, the "stabilized cirrhosis" of Patek (16), were maintained on the low sodium diet (21 mEq. daily). They were then given sufficient albumin

intravenously to raise their serum albumin concentrations to above 3.2 grams per 100 cc. This, or a higher concentration, was maintained throughout the period of study. After a suitable control period on the low sodium intake, each patient was given daily 6 grams of salt (102 mEq. of sodium). Changes in sodium balance and weight in three of the patients are shown in Figures 1-3. Weight changes reflecting the probable alterations in sodium balance on the fourth subject are shown in Figure 4. In all four patients there was a similar

FIG. 2

increase in weight and ascites formation coincident with the administration of added salt. During this period the excretion of sodium in the urine of two patients (C. M. and H. H.) was no greater than during the period of low sodium intake, and was only moderately increased in the third patient (W. M.). As a result, all patients were in a markedly positive sodium balance while receiving supplemental sodium salts. Thus, a normal serum albumin concentration does not alone permit the excretion of excess sodium given orally.

It seemed possible that patients with cirrhosis

FIG. 3

of the liver might react differently to sodium administered intravenously. To study this, two patients, maintained on a low sodium diet, were given sufficient albumin to attain normal serum albumin concentrations and were then given saline intravenously in varying concentrations (C. M. and A. McM., Table I and Figure 5). After a control day, 1,000 cc. of isotonic saline was given intra-

FIG. 4

FIG. 5

venously. The following day, 25 grams of albumin were given and on the fourth day 170 cc. of hypertonic (5 per cent) saline. On the fifth day the albumin was repeated. A marked inability to excrete sodium was noted in both patients following the intravenous administration of isotonic and hypertonic saline. Moreover, diuresis did not occur following the saline administration.⁹ Although patient A. McM. was able to excrete sodium in a more nearly normal manner than C. M., neither subject was able to excrete sodium in high concentrations. Thus, the degree of sodium excretion varies with individual patients. These findings may be contrasted with those of a similar study on a patient with cirrhosis undergoing diuresis after serum albumin therapy (G. C., Table I). The latter was able to achieve sodium equilibrium.

II. The effect of albumin administration on the excretion of sodium (Table II, Figure 6)

Prompt diuresis with rapid loss of both edema and ascites is seen in a few patients with cirrhosis of the liver following the intravenous administra-

⁹ The administration of hypertonic salt solution intravenously in normal individuals stimulates the release of an antidiuretic substance from the pituitary and diminishes urine flow for short periods of time (17). However, the administration of saline in hypo-, iso-, or hypertonic concentrations in normally hydrated individuals, allowed free access of water, results in a considerably increased excretion of water if the urine collections are made over longer periods of time, as in the present study (18).

tion of albumin (7). One such patient (S. P., Figure 6) with marked ascites and massive edema of the lower extremities, scrotum and penis, was selected for study of sodium excretion. He was maintained on a diet calculated to contain 91 mEq. of sodium daily. During the six days prior to the administration of albumin his urinary excretion of sodium averaged only 5 mEq. daily. On the second day of albumin administration (75 grams daily for six days) his urinary sodium excretion rose to 236 mEq. and thereafter averaged 156 mEq. daily. Weight loss began on the first day of albumin administration, and diuresis was sustained until he became free of ascites and edema after 25 days.

Such dramatic results following albumin administration are seen in only a few patients. More commonly, a temporary diuresis and loss of weight follow, or merely a decrease in the rate of weight gain may be observed. A patient (C. M., Table II) whose response fell into the latter category was provided with the low sodium diet to which, after a short control period, 6 grams of salt (102 mEq. of sodium) were added. With this high salt regimen he gained weight rapidly and sodium excretion remained at the control value of about 4 mEq. daily, so that he was in a marked positive sodium balance. Beginning on the sixth day he was given 50 grams of albumin daily for six days and 25 grams daily thereafter. Urinary sodium rose to 21 mEq. daily in the 12th to 14th day pool and subsequently to 40 mEq. daily in the next three-day pool as the serum albumin concentration further increased. However, sodium equilibrium was not achieved, and ascitic fluid accumulation continued. In spite of omitting the added salt for five days, with apparent negative sodium

* The administration of each 25 grams of albumin entails the giving of approximately 15 mEq. of sodium in addition to that in the diet.

balance during this period, a paracentesis became necessary.

Another patient (J. McC., Table II) with recurrent ascites and edema was similarly studied before and during the period of albumin administration. In the control period before albumin administration he was maintained on the low sodium diet during which time urinary sodium averaged 4 mEq. per day. Six grams of salt (102 mEq. sodium) was then added to the diet and the urinary sodium rose in the subsequent five days to an average of 13 mEq. daily with a maximum of 19 mEq. on the fourth day. In the next period 50 grams of albumin were given daily, intravenously. In this period there was an increase in urinary sodium to 35 mEq. on the first day and an average excretion of 57 mEq. per day for the nine days of albumin administration. The increased sodium excretion was followed by a slow diuresis.

A similar study was conducted with patient H. H. (Table II) who also had recurrent ascites. In his case, the low sodium diet was continued throughout without a period of added salt. After a control period of two days, albumin (75 grams daily) was administered, intravenously, for two days and on the third day ascitic fluid was removed by paracentesis. Albumin administration was then resumed for six more days. During the two-day

control period, urinary sodium was 1.0 and 1.3 mEq. daily, rising, after paracentesis, so that on the eighth day of albumin administration it was 9.5 mEq. Positive sodium balance and weight gain occurred during this period in spite of the increase in urinary sodium, since the administration of each 25 grams of albumin entails giving approximately 15 mEq. of sodium.

Data on the three patients shown in Table II demonstrate a considerable variability between patients in the increase of sodium excretion after albumin administration. A negative sodium balance was not achieved in these three patients in spite of albumin administration and the subsequent rise to normal of the serum albumin concentration.

III. The effect of mercurial diuretics on sodium excretion (Table III)

The rate of disappearance of ascites and edema following mercurial diuretics is often as rapid as after albumin administration. To compare the effect of mercurial diuretics on sodium excretion with the effect of albumin, two patients were studied. The first (J. Q.) had massive ascites and edema and a low serum albumin concentration. After a control period on a low sodium diet, he

* 2 cc. "Mercuzanthin" intravenously as indicated (X).

was given 2 cc. of a mercurial diuretic,¹⁰ intravenously daily for five days (Table III). Urinary sodium excretion averaged 9 mEq. daily during the control period, rose to 48 mEq. on the first day of diuretic therapy, and thereafter averaged over 130 mEq. for 12 days. During this period he lost 20 lbs. of weight, and subsequently became free of ascites and edema.

A second patient (C. M.) with chronic, recurrent ascites, and whose serum albumin concentration was low, was given a low sodium diet. Mercurial diuretics were given every other day for eight days, and daily urinary sodium determined (Table III). On the days of mercurial administration, sodium excretion varied between 25 and 62 mEq., while on control days, both between mercurial injections and after they had been discontinued, urinary sodium never exceeded 10 mEq. The patient's weight changed little, however, and the marked diuresis seen in the first study did not occur.

Data on the patients shown in Table III demonstrate that the effect of mercurial diuretics varies in different patients and is possibly related to the relative severity of the liver disease.

IV. Sodium balance in a patient recovering from ascites (Figure 7)

In one patient (W. M.) whose tendency to reform ascites appeared to be overcome, studies were

¹⁰ "Mercuzanthin," Campbell Products, Inc., New York, N. Y.

made of his ability to excrete sodium during the recovery phase. Following a two-month interval, during which he was given maintenance albumin and a general diet unrestricted in sodium, and had had one paracentesis, W. M. was restudied (Figure 7). At this time he was given the low sodium diet and mercurial injections with slight weight loss. On being given the 6 grams of added salt he was able to excrete over 100 mEq. of sodium daily in his urine, sufficient to achieve sodium equilibrium. Very slight weight gain in the first four

FIG. 7

days was recorded, and thereafter in spite of the added salt and further increments to his sodium intake by the administration of 900 cc. of normal saline intravenously daily for two days, weight remained constant. This patient had ceased to form ascites and, in spite of a high sodium intake, was able to excrete it apparently normally. It was previously observed that patient G. C. (Table I), while undergoing diuresis after serum albumin therapy, was likewise able quantitatively to excrete administered sodium.

DISCUSSION

The patients with cirrhosis of the liver and with demonstrable fluid retention reported here excreted in the urine but small quantities of orally or intravenously administered sodium. Positive sodium balance thus inevitably occurred. Sodium excretion increased, occasionally to permit negative sodium balance, in three circumstances: during a spontaneous decrease in ascites and edema formation; following the intravenous administration of albumin; and accompanying the parenteral exhibition of mercurial diuretics. The influence of these circumstances on fluid retention varied greatly from patient to patient. Thus, following intravenous albumin administration one patient who had never required paracentesis had a massive and prolonged diuresis with a marked increase in urinary sodium excretion. In other patients with ascites requiring repeated paracenteses the increased sodium excretion, although evident, was transitory and not great enough to lead to negative sodium balance. Likewise, the effect of mercurial diuretics on sodium excretion and diuresis was variable; one patient achieved a slow but prolonged diuresis with a considerable increase in urinary sodium excretion, while in another the effect was only transitory.

The rate of ascites formation could be altered by changing the quantity of sodium administered to patients with chronic cirrhosis in whom repeated paracenteses were necessary. Thus, a decrease in sodium intake slowed the rate of ascites formation and, conversely, fluid retention increased as more sodium was administered. This relationship held true despite the maintenance in some instances of a serum albumin concentration at or near normal by means of intravenous albumin administration. These observations place on a firmer ground the use of a low sodium diet to reduce the rate of ascites accumulation (19). Such a diet must be prepared with care so that it will furnish an ample supply of calories, protein, and vitamins, and, at the same time be palatable. The preparation and use of such a diet are published elsewhere (20).

A satisfactory explanation of the failure to excrete administered sodium is not at hand. Ralli and her co-workers (3) demonstrated an antidiuretic effect similar to that of pituitrin in the urine of patients with cirrhosis and ascites. How-

ever, retention of sodium is not one of the primary effects of the posterior pituitary antidiuretic substance (21, 22). The observations reported here suggest that sodium excretion is primarily at fault and therefore point rather to the antidiuretic effect of the sex hormones or of those elaborated by the adrenal cortex. It need not be postulated, however, that an antidiuretic is the sole or even most important cause of the failure of sodium excretion in cirrhosis. Other factors such as altered renal blood flow and glomerular filtration are being studied (16). At present too little data are available to draw definite conclusions in this regard.

The results reported here do not precisely define the relative importance in the formation of ascites, of the serum albumin concentration, the portal hypertension, or the failure to excrete administered sodium. Each is undoubtedly important, although recent studies tend to minimize the importance of the serum colloid osmotic pressure (3, 23).

SUMMARY

1. The patients with cirrhosis of the liver with ascites reported in this communication excreted only small quantities of sodium in the urine regardless of either the quantity of salt administered, or the route of its administration (oral and intravenous). The failure to excrete sodium in amounts adequate to achieve sodium equilibrium occurred in spite of the maintenance of a normal serum albumin concentration by repeated injections of concentrated salt-poor human serum albumin.
2. The urinary excretion of sodium was usually increased by the administration of mercurial diuretics or of salt-poor human serum albumin (intravenously) and also during a spontaneous decrease in ascites and edema formation.
3. A low sodium but otherwise adequate diet decreased the rate of ascites formation, while larger quantities of administered sodium led to a proportionately increased rate of formation.
4. Although several factors might have led to the failure of these patients to excrete sodium, there was no evidence that any one was solely implicated.
5. The relative importance of the failure to excrete sodium, of hypoalbuminemia, and of portal

hypertension in the genesis of ascites could not be precisely defined.

ACKNOWLEDGMENTS

The authors wish to express their gratitude to Alice N. Ballou, Ellen V. Cobino, Catherine M. Murphy, and Ellen Doyle for technical assistance, and to Kathleen A. Clinton for preparation of the diets used in this study.

IMPROVEMENT OF ACTIVE LIVER CIRRHOSIS IN PATIENTS MAINTAINED WITH AMINO ACIDS INTRAVENOUSLY AS THE SOURCE OF PROTEIN AND LIPOTROPIC SUBSTANCES^{1, 2}

By RICHARD D. ECKHARDT,³ WILLIAM W. FALON, AND CHARLES S. DAVIDSON

(From the Thorndike Memorial Laboratory, Second and Fourth Medical Services [Harvard], Boston City Hospital, and the Department of Medicine, Harvard Medical School, Boston)

(Received for publication December 6, 1948)

An adequate, nutritious diet is the basic consideration in the treatment of patients with liver disease, particularly cirrhosis (1). However, because of the frequent digestive disturbances encountered in these patients, occasions arise when an adequate intake of nutritious foods cannot be maintained, and complementary or complete nutritional feeding by the intravenous route would appear indicated. Infusions of glucose and vitamins prepared for parenteral use are widely employed, but the desirability of administering protein hydrolysates intravenously to patients with hepatic insufficiency has been the subject of controversy. Thus, it has been stated that amino acids administered parenterally to such patients are not as promptly deaminized and result in a higher incidence of untoward reactions than when administered to normals (2-4), so that "intravenous injection is contraindicated in severe hepatic insufficiency" (5). Nevertheless, since other investigators have been unable to confirm any significant decrease in the rate of deamination of amino acids following their intravenous injection or any increase in untoward reactions (6-9), parenteral protein hydrolysates have been quite extensively employed as a therapeutic adjunct in the treatment of patients with cirrhosis of the liver and with infectious hepatitis (10-12).

The experiments reported here were undertaken to clarify the controversy regarding the desirability of administering protein hydrolysates pa-

renterally to patients with liver disease. Observations were made of the clinical tolerance, the metabolism and excretion, and the therapeutic value of a 10 per cent solution of amino acids administered intravenously in amounts of 500 to 1,000 cc. daily for from two to four weeks as the sole source of nitrogen and of lipotropic substances to four patients with active cirrhosis of the liver. The results indicate that intravenously administered amino acids are well tolerated by patients with severe liver disease, are metabolized and excreted in a manner differing little from normal, and may promote clinical improvement when administered as the sole source of nitrogen and of lipotropic substances.

MATERIALS AND METHODS

The clinical and laboratory observations of the four patients with cirrhosis of the liver selected for this study are tabulated in Table I. Each gave a history of longstanding alcoholism and of meager dietary intake. Three of the patients (B. B., W. C., and J. Q.) were deeply jaundiced and acutely ill at the time the study was begun.

A purified diet adequate in calories but devoid of protein (supplying only 0.1 gram of nitrogen daily as determined by macro-Kjeldahl analysis⁴) was used in all studies. Its composition and ability to maintain nitrogen balance and constant weight with the addition of 85 grams of purified casein ("Labco") as the sole source of nitrogen have previously been described (13). The diet contained no source of the vitamin B complex except choline in small amounts (30 to 100 mgm. daily as estimated from standard food tables). A capsule⁵ containing vitamins A, C, D, B₁, B₂, niacin, B₆, and pantothenic acid was given daily.

Protein was supplied intravenously as a 10 per cent solution of amino acids⁶ prepared by the recombination

⁴ One patient (J. G.) received 15 grams of "Nestle" daily, increasing the nitrogen intake by 0.25 gram.

⁵ "Dayamin" supplied through the courtesy of the Abbott Laboratories, North Chicago, Illinois.

⁶ Developed and distributed by Merck and Company, Inc., Rahway, New Jersey, who supplied the material used in this investigation.

FIG. 1

of fractions of an acid hydrolysate of casein. The product contains no peptides, is essentially devoid of glutamic and aspartic acids, and is supplemented with dl-tryptophane and glycine so that it contains the eight amino acids essential for man (14). The composition of the solution employed (average of the nearly identical lots) and the quantity of amino acids infused are tabulated in Table II. The results are based on analyses by microbiological assay (15).

The basal diet was ingested at regular meal hours. The day's protein (500 to 1000 cc. of the 10 per cent solution of amino acids) was administered in one rapid intravenous injection each morning, usually over a period of one-half to one and one-half hours. Hypertonic glucose (50 to 100 grams) was added to the infusion mixture, and the injection was made one hour after a 1,000 calorie breakfast, in order to achieve maximum utilization of the infused amino acids by the simultaneous provision of adequate carbohydrate and protein (16). The total intake for the four patients during the study averaged 4,500 (J. G.), 1700 (B. B.), 3,500 (W. C.), and 4,200 (J. Q.) calories daily.

The daily urine and pooled stool nitrogen analyses were determined by the standard micro- or macro-Kjeldahl methods. The alpha amino nitrogen was determined by the gasometric ninhydrin method as described by Hamilton and Van Slyke for blood (17), and by Van Slyke, MacFadyen, and Hamilton for urine (18). The serum non-protein nitrogen was determined by Folin's micro-Kjeldahl method with direct nesslerization (19). The urines were assayed for the eight amino acids essential for man and for arginine and histidine by the microbiological method of Stokes *et al.* (15). As measurements of liver function, the serum bilirubin (20), thymol turbidity (21) and flocculation, urine urobilinogen, plasma prothrombin concentration, bromsulphalein retention, and serum albumin concentration (22, 23) were determined. Tissue obtained by punch biopsy ("Vim"-Silverman needle) from the liver of one subject both preceding and following the study period was fixed in 10 per cent

formalin, stained with hematoxylin and eosin, and examined microscopically.

RESULTS

The amino acid mixture was well tolerated clinically. No untoward reactions were noted by patients J. G. and J. Q., even though the infusion of 50 grams of amino acids was usually completed within one hour. A transient diminution of appetite was noted by patient W. C. following several of the infusions, but rarely persisted for more

FIG. 2

than one or two hours. Nausea and retching occurred on three occasions following an attempt at forced feeding of sweetened drinks immediately after the infusion. Patient B. B. complained of constant anorexia that both preceded and followed the present study. Although this digestive disturbance was not aggravated further by infusions of 500 cc. of the amino acid solution, 1,000 cc. infusions, even though administered more slowly, were followed on three occasions by nausea and vomiting. Thrombosis of the infused vein did not occur in any patient. An increased incidence of untoward reactions was not observed while the patients were deeply jaundiced and acutely ill. Despite the severity of the patients' illness and the rapidity of the infusions, distressing symptoms were noted but six times following 79 infusions—a reaction incidence of less than 8 per cent.

The nitrogen balance data for these patients is summarized in Table III and plotted in Figures 1-4. Patient J. G. maintained a positive nitrogen balance throughout the 11 day study period, except for day one. Although the daily infusion of

50 grams of amino acids (500 cc. of the 10 per cent solution) to this subject, together with the diet, supplied slightly less than 0.8 gram of protein per kilogram of body weight, an average positive balance of 3.0 grams of nitrogen daily was realized. Patient W. C. received 100 grams of amino acids (1,000 cc. of the 10 per cent solution) intravenously daily for 18 days and retained a total of 50.8 grams of nitrogen, or an average positive balance of 2.8 grams of nitrogen daily. During a 15 day period while patient B. B. received 50 grams of amino acids parenterally daily, the nitrogen balance averaged +2.2 grams daily, and increased to +7.4 grams of nitrogen daily for five days when the quantity of protein administered was doubled. The excretion of nitrogen in the urine increased little despite the large increase in the quantity of amino acids infused. Patient J. Q. was in slight positive nitrogen balance only during the final six days of a 30 day study period while receiving 100 grams of amino acids intravenously daily. Nitrogen balance was persistently

Thus the negative nitrogen balance persisted unaltered until 100 grams of the amino acid mixture was supplied each day.

The serum concentration of alpha amino and of non-protein nitrogen and the urinary excretion of alpha amino nitrogen in each individual did not vary greatly during the study (Table IV). Since the amino acid content of serum is usually 10 to 40 per cent greater than that of plasma (24), the normal range of alpha amino nitrogen in this laboratory of from 2.9 to 4.6 mgm. per cent for plasma (9) would be increased to from 3.2 to 6.4 mgm. per cent for serum. Although several of the fasting serum alpha amino nitrogen values obtained in the patient (W. C.) receiving 100 grams of amino acids intravenously daily for 18 days were elevated, the values averaged 5.9 mgm. per 100 cc. of serum which is within the normal range.

A slight weight gain occurred in each patient (Figures 1-4). Minimal peripheral edema developed in patient J. G. during the first five days of the study coincident with the inadvertent provision of supplemental salts (5 grams NaCl and 1 gram KCl), and subsided with their cessation. Although sodium, other than that present in the basal diet, was not supplied the other patients, definite peripheral edema occurred in patient J. Q. and increased in degree as the gain in weight continued, and was associated with a fall in the plasma albumin concentration from 2.6 to 1.8 grams per 100 cc. Edema was not discernible in the other patients.

Improvement in liver function tests was observed in all patients during the period of study

FIG. 3

negative throughout a preceding 22 day period while receiving 50 grams of amino acids intravenously daily and a two day period while receiving 75 grams daily. During the protracted period of negative nitrogen balance, the nitrogen-sparing effects of individual amino acid supplements were investigated. The addition of dl-phenylalanine (2 grams) and of dl-threonine (3 grams) individually and combined, given by mouth one hour prior to the intravenous infusion, had no apparent effect on the quantity of nitrogen excreted in the urine.

(Table I, Figures 1-4). A progressive decline in the serum bilirubin, degree of jaundice, and urine bile was the most marked change noted. The thymol turbidity and thymol flocculation tests were found abnormal in three patients before the study, and in each instance showed slight change toward normal. In three instances where the serum protein concentrations were determined before and after the study period, the total protein remained relatively constant, while the albumin rose slightly in one and fell in the others. By physical examination, in addition to a lessening of jaundice, it was noted that the liver size decreased in two patients, and remained unchanged in the others. The spleen became less readily palpable in the two patients with splenomegaly. The degree of ascites, when present, was not appreciably altered.

As mentioned previously, peripheral edema became evident in two patients. In addition to generally improved liver function tests and physical findings, each patient experienced subjective improvement. This was evidenced by increased physical and mental activity, a greater desire to eat, and an enhanced sense of well-being.

Liver punch biopsies obtained from patient W. C. prior to the study and at its conclusion (20 day interval) were reported as follows:⁷

An adequate portion of liver was obtained. The

⁷ The authors gratefully acknowledge the assistance of Norman Zamcheck, M.D., in the pathological interpretation of these specimens. It is regretted that liver biopsy was contraindicated in patients B. B. and J. Q. because of a prolonged prothrombin time (not responding to vitamin K therapy) and deep jaundice.

TABLE II

Composition of the 10 per cent solution of amino acids

	Amounts of amino acids in 500 cc. of the 10 per cent solution*
	grams
Arginine	1.3
Histidine	2.0
Isoleucine	4.2
Leucine	8.4
Lysine	5.2
Methionine	2.0
Phenylalanine	2.1
Threonine	0.9
Tryptophane	0.45
Valine	3.5

* Determinations by microbiological assay (1-form) (15). Also contains: 0.45 gram d-tryptophane, 0.1-0.3 gram glutamic acid, 0.1 gram tyrosine, 11.3 grams glycine, less than 0.03 gram aspartic acid, and (by difference) 3.5 grams non-assayed amino acids per 500 cc. of the 10 per cent solution. Total 10 "essential" amino acids comprise 64 per cent of total amino acids in mixture. Each 500 cc. infusion (by analysis) supplies 44 grams of amino acids, 7.0 grams of total nitrogen, and 6.0 grams of alpha amino nitrogen.

appearance was consistent with portal cirrhosis. Marked fibrosis of the portal areas was noted throughout. A moderate number of lymphocytes and a few eosinophiles were scattered through the fibrous tissue. Bile duct proliferation was prominent. A small amount of fat was scattered in focal areas through the liver parenchyma and the liver cells contained only minimal amounts of glycogen. "Alcoholic hyaline" was found. Many bile thrombi were seen obstructing and distending the bile canaliculi.

The second biopsy obtained 20 days later showed

distinct improvement in the histologic appearance of the liver structure as follows:

Most notable was a marked increase in cell content of glycogen which distended the liver cells so that they appeared to be increased in size and obscured adjoining sinusoids in many areas. There was a decrease in fat although this had not completely disappeared. No bile thrombi were seen. A few cells contained a small amount of green staining pigment and more green pigment was collected in scattered Küpffer cells. Less striking changes consisted of an apparent decrease both in amount of fibrous tissue and of cellular infiltrate of the portal areas.

The loss in the urine of alpha amino nitrogen and of each of the 10 "essential" amino acids following the infusion of the amino acid solution is tabulated in Table V.⁸ There was a loss from ex-

⁸ A portion of the amino acids excreted into the urine is of endogenous source (25). All values listed in Table V are in excess of the amount of alpha amino nitrogen or of individual amino acids excreted by patient W. C. the second day while receiving a 3,500 calorie, protein-free diet prior to the present study. These "endogenous" values were: arginine 8.3; histidine 71.0; isoleucine 5.3; leucine 12.6; lysine 17.4; methionine 4.1; phenylalanine 14.8; threonine 19.1; tryptophane 6.9; valine 7.6; and alpha amino nitrogen 113 mgm. per 24 hours. Although it would have been desirable to obtain "endogenous" amino acid excretion values for each patient, it was not deemed advisable to withhold protein from their diets, particularly since the values for patient W. C. agreed quite closely with those found in the normal (25). Actually, the "endogenous" values are so small in relation to the quantity of amino acids lost following infusions of protein hydrolysates as to be relatively insignificant.

cretion into the urine of from 2.8 to 23.3 per cent of the alpha amino nitrogen administered to the four patients with cirrhosis of the liver. Following daily infusions of 50 grams of the amino acid mixture to patient J. G., and of 50 and 100 grams to patient B. B., only 2.8, 5.7, and 3.7 per cent, respectively, of the administered alpha amino nitrogen was excreted into the urine. The excretion loss was considerably greater, however, following infusions of 100 grams of amino acids daily to patients W. C. and J. Q., and averaged 14.2 and

20.1 per cent, respectively, of the amount given. During the period of persistent negative nitrogen balance while receiving 50 and 75 grams of amino acids daily, patient J. Q. excreted 23.3 and 17.1 per cent, respectively, of the intravenously administered alpha amino nitrogen. In none of the patients did the urinary excretion loss of alpha amino nitrogen correlate with the rate at which the infusion was administered.

There was a considerable variation among patients in the quantity of individual amino acids, as

* Mg. of amino acid or of alpha amino nitrogen in excess of that excreted on a 3,500 calorie, protein-free diet.*

† Per cent of administered amino acid or of administered alpha amino nitrogen excreted in urine. Calculated from the actual composition of each lot used, which differed slightly from the averaged values in Table II.

‡ Values corrected for the supplemental phenylalanine and threonine given during part of this period.

§ Patient B. B. excreted an average of 450 mgm. of alpha amino nitrogen daily for a five day period while receiving 100 grams of amino acids intravenously daily, or 3.7 per cent of the quantity infused.

|| Patient J. Q. excreted an average of 1552 mgm. of alpha amino nitrogen daily for a two day period while receiving 75 grams of amino acids intravenously daily, or 17.1 per cent of the quantity infused.

well as of alpha amino nitrogen, excreted into the urine (Table V). However, it is apparent that certain of the amino acids were more freely lost than were others. Thus, as a group, the patients excreted fairly large percentages of administered threonine and histidine, a small percentage of arginine, and intermediate percentages of the other amino acids. The percentage of individual amino acids and of alpha amino nitrogen given which was lost in the urine by patient J. Q. was as great when 50 grams were given daily and negative nitrogen balance resulted, as when he received twice the quantity and nitrogen equilibrium was attained.

The patterns of the 10 "essential" amino acids in the solution administered intravenously and in the urine are shown in Table VI and plotted in Figure 5. The proportion of the "essential" amino acids in the mixture differed considerably from that excreted in the urine. For example, although arginine and histidine were present in similar proportions in the mixture infused (4.2 and 6.6 per cent of the total 10 "essential" amino acids, respectively), their pattern in the urine was altered so that proportionately far more of the 10 amino acids excreted (average of the four patients) was composed of histidine (15.6 per cent) than of arginine (0.7 per cent). The amino acid pattern

FIG. 5

in the urine following the larger (100 gram) infusions in patients W. C. and J. Q. more closely resembled the pattern of the solution given than that following the 50 gram infusions in patients J. G. and B. B.

DISCUSSION

Patients with cirrhosis of the liver can maintain a positive nitrogen balance if adequate dietary protein is given (26, 27). When an adequate dietary intake of protein can not be maintained, it would appear desirable to provide the protein in a hydrolyzed form intravenously. None of the objections raised to the administration of protein hydrolysates intravenously to patients with liver disease has gone unchallenged, and the present paper suggests that they were unfounded.⁹

I. Clinical tolerance of parenterally administered amino acids in liver disease

For several years in this clinic protein hydrolysates have been administered intravenously as a therapeutic adjunct in the treatment of patients with liver disease. The protein hydrolysates employed (both acid and enzymatically hydrolyzed) were as well tolerated clinically by patients with hepatitis (infectious, toxic, homologous serum),

⁹ Because of improved methods of manufacturing protein hydrolysates, many of the untoward reactions of a decade ago are rarely encountered today. Impressions and conclusions made when less refined products were employed in the past should not necessarily continue to serve as criteria of the value (or lack of value) of hydrolysates now used.

TABLE VI

Comparison of the patterns of the 10 "essential" amino acids administered and excreted following amino acid infusions to patients with liver disease and normal subjects

* Calculated from the quantity of amino acids given, Table II.

† Calculated from the quantity of amino acids excreted, Table V. Excretion pattern of patient J. Q. calculated from 100 grams period.

‡ Average value of eight infusions in normal subjects given 500 cc. of the 10 per cent solution of amino acids intravenously (35).

cirrhosis of the liver (Laennec's, biliary, toxic, pigment), Wilson's disease, liver coma, and obstructive jaundice, as they were by patients with other illnesses or by normal individuals. The relative freedom from untoward reactions following the rapid and repeated daily infusions for from two to four weeks of from 500 cc. to 1,000 cc. of the 10 per cent solution of amino acids to the four patients with severe liver disease observed in the present study confirms the previous impression that amino acids may be administered intravenously with relative impunity to patients with liver disease. The reaction incidence (nausea) of less than 8 per cent noted in the patients with liver disease was similar to that observed in a larger series of individuals following infusions of the same hydrolysate (28).

II. Metabolism of parenterally administered amino acids in liver disease

Evidence that the intravenously administered amino acids were normally metabolized by the patients with liver disease was the positive nitrogen balance attained. Thus, three of the patients (J. G., B. B., and W. C.) maintained a positive nitrogen balance with an average retention of 3 grams of nitrogen daily throughout the period of study. The nitrogen balance in one of these patients increased from +2.2 grams daily to +7.4 grams daily when the quantity of protein administered was doubled. The fourth patient (J. Q.) was in slight positive nitrogen balance while receiving 100 grams of amino acids daily for six days. The latter individual, however, failed to maintain nitrogen equilibrium while receiving 50 and 75 grams of amino acids intravenously daily for 22 and for two days, respectively. Oral supplements of phenylalanine and threonine, amino acids which favor nitrogen conservation in dogs (29), did not alter the negative nitrogen balance. The provision of 50 grams of amino acids to this patient of large stature only represented approximately 0.5 gram of protein per kilogram of body weight which borders on the minimum oral requirement (30). Furthermore, the quantitative requirement of hydrolyzed protein administered intravenously is likely greater than that of an equivalent quantity of whole or of hydrolyzed protein given orally (31, 32). Because the latter patient maintained

nitrogen equilibrium while receiving 100 grams of amino acids intravenously daily, it is suggested that during the protracted period of negative nitrogen balance he received an insufficient quantity of amino acids to fulfill the body protein requirements, particularly in view of the adequate caloric intake maintained throughout the study (4,200 calories daily). Thus, the provision of adequate quantities of amino acids intravenously permitted each of the patients with cirrhosis of the liver to achieve a positive nitrogen balance. The positive nitrogen balance did not reflect a retention of nitrogenous products in the blood, for the serum non-protein nitrogen remained constant throughout the study (Table IV).

Further evidence that the infused amino acids were completely metabolized was the failure to observe a progressive rise in the serum alpha amino nitrogen concentration in the patient receiving 100 grams of amino acids intravenously daily for 18 days (W. C., Table IV). Although the ability of an impaired liver to deaminate promptly intravenously administered amino acids has been questioned, the blood amino acid values following infusions of protein hydrolysates do not differ greatly in normals and in patients with liver disease, as shown in Figure 6. Thus, patients with liver disease are able to metabolize intravenously injected amino acids promptly and completely, whether given once as in the "tolerance tests" reported in the literature (2, 7-9) and plotted in Figure 6, or given repeatedly as in the present study.

FIG. 6

The significance of the slight weight gain observed in each of the patients (Figures 1-4) is difficult to evaluate. Gain in weight was associated entirely in one patient (J. Q.) and, at least in part, in a second (J. G.) with fluid retention, since both developed minimal peripheral edema during the study. Since patients with "decompensated" cirrhosis of the liver have an avidity for sodium and water (33), it can not be stated with certainty that fluid retention did not occur in all of the patients in this study.

III. *Excretion of parenterally administered amino acids in liver disease*

It was reported previously from this clinic that the average daily excretion of alpha amino nitrogen and of the 10 "essential" amino acids in the urine of patients with severe liver disease eating *ad libitum* did not differ markedly from normal subjects, although there was considerable variation among patients in the quantity of individual amino acids excreted (34). Similarly, the "endogenous" excretion of amino acids by patient W. C.^a was similar to that found in the normal (25). The present study presents further evidence that parenterally administered amino acids are excreted in patients with severe liver disease in a manner differing little from normal. The loss of alpha amino nitrogen in the urine by the patients with liver disease (Table V) was similar to that observed in a previous study in normals following infusions of equivalent quantities of the same hydrolysate (35). Thus, there was an average urinary loss following 500 cc. infusions of 9 per cent (range 3 to 13 per cent) of the amino nitrogen administered to normal subjects and of 3 and 6 per cent to patients with liver disease (J. G. and B. B.). The urinary loss of amino nitrogen following 100 gram amino acid infusions averaged 14 per cent (range 9 to 19 per cent) in normals and 4, 14, and 20 per cent in patients with liver disease (B. B., W. C., and J. Q.). Furthermore, as in the normal individuals, the urinary excretion loss of alpha amino nitrogen of the patients with liver disease correlated more closely with the size of the infusion than with the speed at which it was given. A progressive increase in the urinary excretion of alpha amino nitrogen did not occur in any patient during the study (Table IV).

The observation that patients with severe liver disease excreted fairly large percentages of administered threonine and histidine and smaller percentages of the other amino acids following infusions of the amino acid solution is further evidence that amino acid excretion in liver disease is normal, since these amino acids were similarly excreted following amino acid infusions in normal subjects (35). Furthermore, the post-infusion pattern of the "essential" amino acids excreted in the urine of the patients with cirrhosis was similar to that in normals, although the individual amino acids were not excreted in the same proportion as administered in either group (Table VI, Figure 5). The excretion pattern following the larger (100 gram) infusions in the patients with liver disease more closely resembled the pattern of the solution given than that following the 50 gram infusions. It was previously observed in normals that the amino acid pattern following rapid infusions of the amino acid solution more closely resembled the pattern of the amino acids given than that following infusions given more slowly (35). Thus, the administration of amino acids intravenously slowly and in small quantity is followed by excretion in the urine of but minimal amounts of amino acids in a pattern differing from the pattern of the amino acids given, while the infusion of amino acids rapidly and in large amounts results in a greater excretion loss of alpha amino nitrogen and of individual amino acids in a proportion quite similar to that in the solution administered. As discussed previously (35), an interpretation of these observations is not possible until further data relating to renal clearance studies in man are available. Nevertheless, the similarity in the renal excretion of amino acids by normals and by patients with liver disease is apparent.

IV. *Therapeutic value of parenterally administered amino acids in liver disease*

Improvement in the liver disease was observed in all patients during the period of study, as evidenced by a progressive decline in the serum bilirubin, degree of jaundice, and urine bile in each patient, a decrease in the size of the liver and spleen in two patients, and a distinct improvement in the histologic appearance of the liver structure in the second biopsy obtained in one patient. The im-

provement in the liver function tests and physical findings was as marked when insufficient amino acids were administered intravenously and negative nitrogen balance resulted (patient J. Q., Table I and Figure 4), as when sufficient amino acids were available to attain positive nitrogen balance. This finding suggests that improvement in liver function in man can proceed even in the face of a negative nitrogen balance, perhaps as a result of mobilization of tissue proteins. That repair of injured tissue can take place during periods of insufficient dietary protein intake and negative nitrogen balance by the diversion of nitrogen from one organ of the body to another finds support in several studies. Thus, some replacement of liver protein occurs in partially hepatectomized rats maintained on a protein-free diet (36), blood regeneration proceeds satisfactorily in anemic animals and man during periods of negative nitrogen balance (37, 38), and considerable tissue repair (fibroplasia) occurs in the experimental wounds of rats maintained on a low protein diet (39) and presumably also during the "catabolic period" after damage in man. Under these circumstances, however, an adequate protein intake and retention would be necessary in order to replace the depleted tissue protein, and perhaps to enhance repair of the injured tissue.

Further studies in man are needed to determine whether liver repair is more satisfactorily achieved by an adequate rather than by an inadequate protein intake, or by diets containing supplements of additional protein or of "lipotropic" substances. The present study does demonstrate, however, that liver repair in man can proceed when amino acids, even in amounts insufficient for nitrogen equilibrium, are administered intravenously as the sole source of nitrogen and of lipotropic substances except for small amounts of choline.

Post and Patek observed that patients with cirrhosis of the liver absorb and retain food protein as do patients with simple protein starvation, and differ from the latter group only by an impaired ability to synthesize serum albumin (27). The difficulty of increasing the serum albumin concentration in undernourished patients with chronic liver cirrhosis by feeding a nutritious diet high in protein is well established (40, 41). Thus, it is not surprising that the serum concentration of total

protein and of albumin did not rise in the patients during the present study (Table I).

It should be emphasized that the present study was undertaken to determine the clinical tolerance, metabolism and excretion, and therapeutic value of amino acids administered intravenously to patients with liver disease. It is neither the authors' intent nor desire to suggest that patients with liver disease receive each day a synthetic protein-free diet by mouth, and 50 to 100 grams of amino acids by vein as the sole source of nitrogen and of lipotropic substances. We firmly believe that therapy in liver disease is based upon the fundamental principle of insuring that nutritious food is eaten, digested, and absorbed. When an adequate intake of nutritious foods can not be maintained, however, the results of the present study indicate the desirability of providing the protein nutrients intravenously as amino acids.

SUMMARY

1. Four patients with active cirrhosis of the liver were given a protein hydrolysate intravenously daily for from two to four weeks as the sole source of nitrogen. A purified diet furnished adequate calories, but only small amounts of choline.

2. The amino acid solution (50 to 100 grams of amino acids) was administered in one rapid injection each morning and was well tolerated clinically.

3. The provision of adequate quantities of amino acids intravenously permitted each of the patients to achieve a positive nitrogen balance which was not associated with azotemia or hyperaminoacidemia.

4. There was a loss into the urine of from 3 to 23 per cent of the alpha amino nitrogen administered. This loss correlated more closely with the size of the infusion than with the speed at which it was given, and did not progressively increase in any patient during the study. The individual amino acids were not excreted in the urine in the same proportion as administered, so that as a group the patients excreted fairly large percentages of administered threonine and histidine, a small percentage of arginine, and intermediate percentages of the other amino acids. These data are similar to those observed in normals.

5. Improvement in the liver disease was observed in all the patients during the period of study, as evidenced by a progressive decline in the serum bilirubin, degree of jaundice, and urine bile in each patient, a decrease in the size of the liver and spleen in two patients, and a distinct improvement in the histologic appearance of the liver structure in one patient.

6. Improvement in liver function tests and physical findings was even observed in one patient who received insufficient amino acids and was in negative nitrogen balance for three weeks. This finding suggests that improvement in liver function in man can proceed even in the face of a negative nitrogen balance, perhaps as a result of mobilization of tissue proteins.

7. It is concluded that intravenously administered amino acids were well tolerated by these patients with severe liver disease, were metabolized and excreted in a manner differing little from normal, and permitted clinical improvement although administered as the sole source of nitrogen and of lipotropic substances.

ACKNOWLEDGMENTS

The authors wish to thank the Misses Alice Ballou, Ellen Cobino, Ellen Doyle, Elaine Hirshberg, and Catherine Murphy for their technical assistance, and Miss Kathleen Clinton for preparing and calculating the diets used.

THE EFFECTS OF DIHYDROERGOCORNINE ON THE CIRCULATION IN THE EXTREMITIES OF MAN

By DANIEL W. HAYES,¹ KHALIL G. WAKIM, BAYARD T. HORTON,
AND GUSTAVUS A. PETERS

(From the Divisions of Medicine and Physiology, Mayo Foundation and Mayo Clinic,
Rochester, Minnesota)

(Received for publication September 28, 1948)

Since the advent of therapeutic surgical procedures on the autonomic nervous system, increased interest has been shown in drugs which block this fairly complex and enigmatic part of the nervous system. One of these drugs is a derivative of ergot, called dihydroergocornine (DHO-180). Some of its clinical applications have been reported by several workers, (1-6), showing principally its effects in hypertension, in which a lowering of blood pressure was obtained. Bluntschli and Goetz (2, 5) reported cases in which they recorded toe and finger volume, pulse volume and rate, and skin temperatures before and after administration of dihydroergocornine. They stated that vasodilatation and reduction of blood pressure in both normal and hypertensive subjects were produced through functional blocking of sympathetic impulses by the drug.

Ergot of rye has long been separated into component parts and many substances have been obtained from the crude drug. Stoll and his co-workers (7-9) have shown that ergot contains three alkaloidal groups, and six natural alkaloids, each of which has two isomeric forms. The three groups, and the alkaloids contained therein, are the ergotamine group, containing ergotamine and ergosine; the ergotoxine group, made up of three alkaloids, ergocristine, ergokryptine and ergocornine; and the third group with only one alkaloid, ergobasine. These alkaloids have similar chemical structures and can be transformed into dihydrogenated forms. The latter have been found to be less toxic than the natural alkaloids.

Since dihydroergocornine has been reported to have vasodilator properties by virtue of its purely sympathicolytic action (2, 3, 5, 6), we deemed it interesting to investigate its effects on the peripheral circulatory system in man, under carefully controlled laboratory conditions.

¹ Fellow in Medicine, Mayo Foundation.

METHODS

A group of 20 patients with various primary diagnoses, including Ménière's syndrome, multiple sclerosis, headaches of various types and hypertension, volunteered for this study. The ages varied between 20 and 63 years.

Before the observations were begun, the patient reclined quietly on a comfortable test bed for at least 30 minutes, in a constant temperature room at 77° F. with a humidity of about 40 per cent. The blood flow in all four extremities was measured by means of the venous occlusion plethysmograph with a compensating spirometer recorder (10). The arm plethysmograph included the hand, wrist, forearm and part of the arm up to 2 inches (about 5 cm.) above the olecranon process. The leg plethysmograph included the foot, ankle and leg up to 1 inch (about 2.5 cm.) below the tibial tuberosity. Finger and toe pulses were recorded by means of digital plethysmographs on the right and left index fingers and on the right and left second toes.

The heart rate and the systolic and diastolic blood pressures were recorded by means of the usual clinical procedures. Control values were established for heart rate, blood pressure and blood flow before the drug was given. These observations were again repeated at regular intervals during a period averaging 65 minutes and ranging from 15 to 85 minutes after the drug had been administered. However, when the drug was given by infusion over a period of 20 minutes, additional observations were taken during the period of infusion.

Dihydroergocornine was given in total doses from 0.25 mg. to 0.4 mg. The dose varied from 0.0038 mg. to 0.008 mg. per kilogram of body weight. In six cases the drug was given by continuous intravenous infusion in physiologic saline solution containing 0.5 mg. dihydroergocornine (DHO-180) per 100 cc. and was administered over a period of 20 minutes. In 14 other cases the drug was given in a single dose by intravenous injection.

RESULTS

Table I presents the changes in blood flow in the upper and in the lower extremities as well as the changes in heart rate and blood pressure of subjects who were given dihydroergocornine by intravenous infusion in the amounts specified. The average increase in blood flow was 117 per cent for both upper extremities with a range of 35 to

* Hypertensive cases.

† Exclusive of cases 8 and 19.

blood flow of the upper extremities. The overall average increase in blood flow for the entire group of 20 cases was 94 per cent in the upper extremities and 68 per cent in the lower extremities.

At an average time of 65 minutes after the drug had been given, final readings still showed a definite increase in blood flow in all four extremities.

There was no significant change in the systolic or diastolic blood pressure readings in any of the 17 normotensive patients. However, in the two hypertensive subjects (cases numbered 8 and 19 in the tables) there was a significant and marked fall in the blood pressure of both subjects. The maximal change occurred between 30 and 45 minutes after the drug had been given. Tables I and II give the changes of blood pressure on the individual cases.

The heart rate decreased in every case after dihydroergocornine was administered. The average decrease was 13 beats per minute, with a range of 2 to 32 beats per minute. Tables I and II give the changes in heart rate in the individual cases.

No toxic or cumulative effects were noted in the three patients who were given the drug from eight to 20 times once daily on successive days by infusion of 0.5 mg. of dihydroergocornine (DHO-180) in 100 cc. of physiologic saline solution.

Side reactions were common and were noted in 19 of the 20 cases, but none were serious. Seventeen patients complained of nasal congestion, which in most cases produced severe obstruction of the nasal passages. This occurred within 25 minutes after dihydroergocornine had been given and usually lasted for about two hours. Benadryl, given to a few subjects, had no effect on reducing this congestion. Mild to moderate nausea occurred in seven cases and vomiting in only one case. Headache occurred in six cases and was moderately severe. A sensation of flushing occurred for a few minutes in four cases. Four patients experienced a sudden urge to urinate. This occurred at the peak of action of the drug and was not observed in other cases during equally long and similar periods when no drug was given. No flushing of the exposed skin surface nor sweating were noted in any of the cases. No pupillary changes occurred.

Figures 1 and 2 show typical blood flow curves before and at the height of action of the drug. Figure 3 shows the increase over the control in

amplitude of the pulse in the fingers and toes after the administration of dihydroergocornine. The pulse tracings of the right and left index fingers and of the right and left second toes of 17

of the 20 patients were taken before and at regular intervals after dihydroergocornine had been administered. There was an increase in the amplitude of the pulse in every case—in only one was

the increase considered slight. Figure 4 shows the changes in blood pressure, heart rate and blood flow in a representative case.

COMMENT

The mechanisms by which dihydroergocornine exerts its effects are as yet not entirely clear.

EFFECT OF DIHYDROERGOCORNINE ON DIGITAL PULSE VOLUME

FIG. 3. FINGER-PULSE AND TOE-PULSE VOLUME RECORDINGS BEFORE AND 20 MINUTES AFTER INTRAVENOUS INJECTION OF DIHYDROERGOCORNINE

Note the increase in pulse volume after the drug had been given.

FIG. 4. BLOOD PRESSURE, HEART RATE AND PERIPHERAL BLOOD FLOW BEFORE AND AFTER DIHYDROERGOCORNINE WAS GIVEN INTRAVENOUSLY

Rothlin (11) stated that dihydroergocornine has central and peripheral effects. Its effect on lowering body temperature is of central origin, since it may be blocked by general anesthesia. He further stated that the dihydrogenated alkaloids have a constrictive effect on isolated arteries, blood vessels in the rabbit's ear and in the extremities of the frog. However, in addition to this direct effect on the vessels, there is a latent central sympathicolytic action. He did not observe any visible or latent effects on the isolated heart.

In pithed animals the blood pressure is raised by direct vasoconstrictive action on the vessels, but in the intact animal the blood pressure is lowered and there is a reversal of the epinephrine effect after administration of dihydrogenated alkaloids. Thus the action of dihydroergocornine on the blood vessels in animals is bivalent in that central and peripheral mechanisms are present and act in competition with each other. The fall of blood pressure produced by the natural alkaloids is related to the inhibition of the vasomotor center; the fall in blood pressure produced by the dihydrogenated alkaloids is attributed to stimulation of a vasodilator center. Rothlin (11) attributed the decrease in heart rate to central stimulation of the vagal center.

As is seen from the findings in this study, dihydroergocornine produced an increase in the blood flow in the extremities in all but one case. The increase in blood flow in the extremities is indicated by the plethysmographic findings as well as by the increase in the amplitude of the pulse tracings.

From the studies presented here, no accurate statement can be made as to the site of action of dihydroergocornine. Bluntschli and Goetz (5) presumed the site of action to be "in the medulla and/or hypothalamus."

Side effects in our series were more common than previously reported (1-3, 5, 6) and occurred with lower dosages. Because of this fact we decided against the use of doses larger than 0.4 mg.

Conclusions about cumulative and toxic effects of the drug cannot be made from this study since only three patients were given the drug more than once.

SUMMARY AND CONCLUSIONS

The effects of the intravenous administration of dihydroergocornine, an alkaloid of ergot, on the blood pressure, heart rate and peripheral blood flow were studied on 20 human volunteers. The drug was administered to six patients by intravenous infusion of a solution containing 0.5 mg. of dihydroergocornine per 100 cc. of physiologic saline solution, and to 14 patients by a single intravenous injection. The total dose varied from 0.25 mg. to 0.4 mg. The blood flow was determined by means of a venous occlusion plethysmograph with the compensating spirometer recorder.

Dihydroergocornine produced an over-all average increase in peripheral blood flow of 94 per cent in the upper extremities, and 68 per cent in the lower extremities. In one case the blood flow in the upper extremities decreased 3 per cent.

The blood pressure fell in the two hypertensive cases after administration of dihydroergocornine. In normotensives there was no significant change in blood pressure.

The heart rate decreased in every case with an average reduction of 13 beats per minute.

Side reactions were more common than previously reported even with lower dosage. Nasal congestion, nausea, headache, flushing, an urgency for urination and vomiting were the side reactions observed.

STUDIES OF COPROPORPHYRIN. IV. THE PER DIEM EXCRETION AND ISOMER DISTRIBUTION IN THE URINE IN INFECTIOUS HEPATITIS, INFECTIOUS MONONUCLEOSIS, AND MECHANICAL JAUNDICE¹

By CECIL JAMES WATSON, VIOLET HAWKINSON, RICHARD B. CAPPS,²
AND EMANUEL M. RAPPAPORT³

(From the Department of Medicine, University of Minnesota Hospitals, Minneapolis, and the DeWitt and Schick U. S. Army General Hospitals⁴)

(Received for publication December 29, 1948)

The occurrence of increased amounts of porphyrin in the urine in cases of liver disease was first duly emphasized by Archibald Garrod (1, 2). Garrod believed this to be hematoporphyrin, a confusion with coproporphyrin which was corrected by H. Fischer and Zerweck (3), and which undoubtedly depended upon the very close similarity of the absorption spectra of the two porphyrins. When examined with the relatively crude spectroscopes available at the time of Garrod's study, these porphyrins were indistinguishable. The investigations of H. Fischer, however, made it clear that hematoporphyrin does not occur in the urine, if, indeed, it occurs as a natural product at all. Studies of urinary porphyrin excretion in liver disease, subsequent to that of Garrod, have been for the most part of rather fragmentary nature, consisting of one or not more than a few examples of any one affection. The pertinent literature has been reviewed within recent years (4, 5) and need not be considered here. Attention may be drawn, however, to the papers of Nesbitt and Snell (6, 7) and Localio and co-workers (8), in which considerable data were reported on the feces-urine ratio of coproporphyrin both in obstructive jaundice and liver disease. The papers of Watson (9, 10) and Dobriner (11) present limited data on

the urinary isomer distribution (ratio of types I and III) in these conditions. Dobriner made several important observations in cases of catarrhal jaundice, obstructive jaundice, and cirrhosis of the liver, to which reference will be made again, in this and subsequent papers of this series. Studies of isomer distribution have been generally discouraged, however, by the lack of a method of isomer analysis applicable to small volumes of urine, and as a corollary of this, the lack of exact knowledge of the isomer distribution in normal urine. In previous papers a suitable method has been described (12, 13) and in paper I of this series (14) the results of the application of this method to normal urine have been given. The purpose of the present investigation was to determine the total urinary coproporphyrin (UCP) as well as the isomer distribution in 24-hour samples from cases of infectious hepatitis at various stages of the disease, and also, for purposes of comparison, from cases of infectious mononucleosis and of mechanical jaundice, the latter term being used to designate jaundice due to extrahepatic biliary obstruction, or obstruction of the main hepatic ducts in the liver. It was also desired to assay the value of the UCP determination, relative to other methods of studying liver function, as an indication of residual hepatic functional impairment in cases of hepatitis at various periods after the disappearance of jaundice.

MATERIAL AND METHODS

The method of Schwartz and associates (13) was used to determine the UCP and the isomer distribution. Recent evidence indicates that the true value for the UCP is approximately 20 per cent higher than that obtained with this technique. Nevertheless, all of the data given in the following may be compared directly with the normal data given in paper I (14).

The fractional serum bilirubin was determined according to the modification of the Malloy-Evelyn method

⁴ Formerly at Auburn, California, and Clinton, Iowa, respectively.

described by Ducci and Watson (15). The bromsulfalein retention in the blood was determined according to Mateer (16), 45 minutes after injection of 5 mg. of the dye per kilo of body weight. The cephalin cholesterol flocculation test was performed according to Hanger (17). Cholesterol and cholesterol esters were determined by the method of Sperry and Schoenheimer (18). In some instances the urine urobilinogen was determined in 24-hour urine samples (19); in others the quantitative urine Ehrlich reaction (20, 21) was carried out on individual or two-hour samples. The number of coproporphyrin determinations and the cases which were studied are given in Table I.

As noted in Table I, the determinations were often repeated, either with relation to stage of the disease or fluctuation of the jaundice, or in some instances within a brief interval, for purposes of corroboration. The majority of determinations in the infectious hepatitis group were in the period after the disappearance of jaundice.

RESULTS

The data obtained in the five groups of cases (as noted in Table I), are given in Tables II-VI, respectively. The data in Table II permit some comparison of the UCP in cases of hepatitis, with the results of other tests of liver function, as well as

TABLE I
*Composition of clinical material and
number of determinations*

Group	Diagnosis	Number of cases	Number of determinations of UCP	Isomer analyses
1	Infectious hepatitis*	96	172	53
2	Infectious mononucleosis†	25	25	16
3	Cancer of pancreas or bile ducts	41	46	38
4	Common duct stone or stricture	30	49	30
5	Cirrhosis (all types)‡	48	95	53

* This group includes cases of epidemic hepatitis and homologous serum jaundice, some of which were studied in Minneapolis, and some at the Schick and DeWitt General Hospitals of the U. S. Army, at Clinton Ia., and Auburn, Cal., respectively; the urine porphyrin studies were carried out in all instances in Minneapolis. The group also includes cases of epidemic and homologous serum jaundice, and of sporadic hepatitis studied in Minneapolis.

† These cases were studied on the Health Service of the University of Minnesota Hospital, Dr. Ruth Boynton, Director. Liver function studies in this group have been reported elsewhere by Dr. Ralph Peterson (26).

‡ The cirrhosis data will be considered in detail in the ensuing paper of this series, but are included in the present communication for purposes of comparison, with particular respect to the differential diagnosis of jaundice.

UCP in Relation to Duration of Jaundice and Interval after Disappearance of Jaundice

rial includes but one instance of what was believed to represent hepatitis without jaundice (Case 2 in Table II). The upper limit of normal of 100 γ , as indicated in Figure 1, was established with relation to the value of the mean plus two standard deviations, or 97 γ . One instance of the 53 in the normal group was above this value, with 99 γ (see paper I of this series [14]).

As shown in Figure 1 and Table II, a number of the cases of hepatitis were first seen in a late stage of the disease, weeks or months after the

disappearance of jaundice. At least two of these are sufficiently instructive to be given in more detail in the following:

1. Case 45, A. G., male 21, farmer. The patient was first seen at the University Hospital on March 11, 1946. He stated that about six months earlier he developed nausea and anorexia, shortly followed by jaundice which persisted for two months. During the last four months he felt fairly well and had resumed his work, but was bothered by persistent discomfort and tenderness in the right upper abdomen. Examination revealed an enlarged tender liver and a palpable spleen. Routine laboratory studies were normal. As seen in Table II, the fractional serum bilirubin, thymol turbidity, cephalin cholesterol flocculation, bromsulfalein, cholesterol and ester percentage, were all within normal limits. The serum proteins, hippuric acid synthesis, and prothrombin time were also normal. The urine Ehrlich test on individual samples was normal, but the 24-hour urine urobilinogen was 10.4 mg., in other words, considerably elevated. The UCP was markedly increased, usually above 200 $\gamma/24$ hours (see Table II). The liver biopsy revealed evidence of an active hepatitis, *i.e.*, small foci of cellular exudate with occasional necrosis, but no fibrosis.

2. Case 49, V. A., male, 41, illustrator. This

case is presented in more detail because of the unusually favorable opportunity for study that was presented during the latter weeks of a prolonged "catarrhal" jaundice or sporadic infectious hepatitis. Following is a brief summary of the salient clinical features:

The first day of observation, Figure 2, was February 24, 1947. At this time the patient had been jaundiced for two months. On December 7, 1946, he experienced an acute attack of diarrhea, nausea and vomiting, of 12 hours' duration. He recovered and felt quite well, but on December 26, he noted fever, malaise, and pain in the muscles. His urine became dark, and he consulted a physician who made a diagnosis of infectious jaundice. When first seen at the University Hospital the liver was moderately enlarged and tender. Within three weeks the tenderness had disappeared and the jaundice had markedly diminished. The liver was still palpable. By April 8, the jaundice had disappeared though the serum bilirubin was still distinctly elevated. Although the patient's appetite had returned, a moderate lassitude persisted throughout the summer. He did not have energy enough to play golf which he ordinarily enjoyed. By November of 1947, however, he believed that he had regained an entirely normal status. As noted in Figure 2, the results of the liver function studies, except the UCP, were normal by the 65th day of observation (corresponding to April 30, 1947). The UCP, however, remained considerably elevated, the value on the 171st day (August 14, 1947), being 253. Later determinations have continued to show abnormally high values, as seen in Table VII. The patient feels quite well (December 15, 1948) but has now developed a number of small spider nevi over the neck, upper chest, and hands. The liver is palpable at the costal margin, not tender.

The total coproporphyrin values together with the percentage and actual amount of each isomer as determined in 46 cases of infectious hepatitis, are given in Table III. Similar data for the infectious mononucleosis group are shown in Table IV. In Figure 3, the initial values obtained for the total UCP and per cent of type III isomer, in the first 40 cases of hepatitis to be studied in this way, are plotted in comparison with the values for the normal (Minneapolis) series previously reported (14), and for 38 cases of acute poliomyelitis.

UCP and Other Liver Function Studies

FIG. 2

UCP and Percentage of Type III Isomer
in Poliomyelitis and Infectious Hepatitis

FIG. 3

The latter data have also been reported previously (22) and are included here only for purposes of comparison with the results in the hepatitis cases. One instance was of particular interest because of the likelihood of coexistence of infectious hepatitis and poliomyelitis.

Case 51, L. H. female, 32, housewife. This patient was seen during the epidemic of poliomyelitis in 1946. She complained of headache and stiff neck, and there was fever. The spinal fluid was found to contain 17 mononuclear cells per cu. mm. When first seen, there was distinct jaundice, in ad-

dition to the findings indicative of poliomyelitis. A history was obtained of painless jaundice suffered by her son and several individuals in the neighborhood about six weeks earlier. The patient had observed dark urine at the outset of her own illness. The liver was not palpable or tender at any time. The laboratory data as seen in Table II revealed marked liver functional impairment. The first UCP on September 4, was 265 γ /24 hours; three days later it was 642 γ , and at this time 82 per cent was type I, the remainder type III. This represents 116 γ of type III. In paper I of this

series, it was noted that 31 γ was two standard deviations above the mean for the normal group. Thus it is evident that there may be a marked increase of one isomer, even though, percentagewise, the other one is preponderant.

Tables V and VI include the data for the biliary tract cancer and the calculous groups respectively. Two exceptional cases included in Table VI deserve individual consideration. Both of these exhibited considerable increases of type III isomer in contradistinction to the other members of the group, in which the increase was mainly of type I. In both, however, there were prominent features serving to distinguish them in other respects as well. In Case 2, gallstones were found in a large

sub-hepatic pocket resembling an abscess; the gall bladder and common duct were not identified and the surgeon believed that there had been a severe inflammation with considerable "breaking down of tissue." The spleen, which was removed, weighed 1270 gm., and was diagnosed as splenic hyperplasia or Banti's disease; liver biopsy revealed a definite early cirrhosis. It was impossible to obtain a history of alcoholism or other chemical exposure which might have explained the excessive type III coproporphyrin excretion in this case. The possibility of endogenous chemical intoxication is considered because of the above operative findings.

In Case 12, Table VI, necropsy revealed miliary

tuberculosis. The possible relationship of this condition to an excessive type III coproporphyrin excretion is not clear and is receiving further study. Again one must consider an endogenous chemical intoxication, due to extensive necrosis, as the important factor.

A third case, not included in the tables, and which we have not been able to classify, was that of an aeronautical engineer, a male, 47 years of age, who was conducting research at very low temperatures. In fact, 24 hours before the onset of his illness, he had spent an hour and a quarter in a cold chamber at -60°F , wearing a suit specially designed for high-altitude flying. The temperature of

his skin, measured by means of a thermocouple, fell to as low as 84°F during the latter part of the experiment. He felt fairly well until the next day when he noticed marked aching in the muscles. This persisted and the next day his temperature rose to 103°C . Two days later he became jaundiced; the urine was dark and the stools light. The jaundice became more marked and persisted about two weeks, the maximum serum bilirubin being 6.8 mg. per 100 cc., of which 3.7 mg. was the prompt direct (one minute) type. The cephalin cholesterol flocculation test was 3 plus. The 24-hour urine urobilinogen was 113 mg. The UCP was 270 $\gamma/24$ hours of which 90 per cent was the

type III isomer. The attack was relatively mild and the patient felt quite well six weeks later. This would in all likelihood have been accepted as an episode of sporadic infectious hepatitis if it were not for the curious circumstances at the outset, coupled with the result of the porphyrin determination. The former might be regarded simply as a precipitating factor, but it was then found that there had been considerable alcoholism in the weeks or months preceding the onset of the jaundice, also that there had been moderate exposure to a number of chemicals and heavy metals in connection with the patient's research. Furthermore, the excessive type III coproporphyrin excretion persisted long after the attack of jaundice which has just been described. On March 8, 1946, nearly two years later, the UCP was 208 $\gamma/24$ hours with 65 per cent type III; on August 14, 1946, it was 187 γ ,

and on November 23, 1946, 175 γ . Thus, while it was impossible to classify this case, it appeared reasonable to believe that it was more likely due to extrinsic chemical and possibly physical factors, and less likely to an infectious hepatitis, although a combination of chemical and viral factors is a distinct possibility.

DISCUSSION

The present results reveal that the urinary coproporphyrin is quite uniformly increased in regurgitation jaundice, whether due to biliary obstruction or to parenchymal hepatic disease. Further study is necessary to determine if this is due only to regurgitation of bile into the blood stream, or to hepatocellular functional impairment, or to a combination. The persistent and often marked elevation of the urinary coproporphyrin long after the disappearance of jaundice points toward an hepatocellular or retention, rather than a cholangiolar or regurgitation factor. The elevated values in obstructive jaundice, however, are perhaps indicative of the latter, particularly inasmuch as they were observed in relatively early cases before one would anticipate significant hepatocellular functional impairment. Van den Bergh (23) was impressed by the coproporphyrinemia and increased coproporphyrinuria in mechanical jaundice, and ascribed them to regurgitation of bile into the blood. Gonzalez-Oddone, working in this laboratory, has observed⁵ that intravenously injected coproporphyrin appears in the thoracic duct lymph of dogs having ligated common bile ducts, in this respect behaving like injected bromsulfalein (24). Thus it appears that, in cases of jaundice, the coproporphyrin may appear in the urine in excess as a result either of hepatocellular or cholangiolar impairment, in the first instance probably being retained and in the second, regurgitated from the intrahepatic biliary system into the blood. The fact that the highest values are more likely to be encountered in jaundice due to hepatitis or cirrhosis may indicate a combination of these factors in such cases. This is quite in harmony with the belief that in hepatitis, there is both hepatocellular and cholangiolar injury, varying in severity in different instances and at different stages in the same instance (25).

It is appropriate to ask whether the increased

⁵ Unpublished observation.

amounts of coproporphyrin I in the urine of the present series of cases represents actual overproduction of this porphyrin, or merely a diversion of that which would normally be excreted in the bile and thence in the feces. There is actually no evidence of over-production. It has already been seen that the factors of retention and regurgitation are probably operative in reducing the biliary excretion of coproporphyrin and increasing its excretion in the urine. The amounts in the urine in these cases do not exceed those of the normal feces in 24 hours. Thus the evidence so far available indicates simple diversion rather than over-production, at least in the majority of cases in which type I is preponderant in the urine. This may be true as well for other conditions in which increased amounts of coproporphyrin I are found in the urine. Simultaneous studies of fecal and urinary excretion are needed, however, before the question can be answered with certainty. The available evidence at the present time (4, 5) indicates that there are but two conditions under which an overproduction of the type I isomer may be anticipated: (1) porphyria, a constitutional metabolic fault; (2) increased erythropoietic activity following increased blood destruction or blood loss. In the case of the type III isomer, it is clear that there is often marked overproduction and increased excretion from various causes (5).

It appears unlikely that a determination of the total urinary coproporphyrin will frequently be of value in the distinction of parenchymal jaundice from jaundice due to extrahepatic biliary obstruction. Careful study of the data obtained in the present study reveals considerable overlapping of values at various levels of icterus due to biliary obstruction as compared with diffuse liver injury. In Figure 4 the values for UCP in the cancerous, calculous, and hepatitis-cirrhosis groups are plotted against the values for total bilirubin. The data for the cases of cirrhosis included in this figure are considered in more detail in the subsequent paper of this series. It is seen in Figure 4 that while there is no distinct cleavage between the hepatitis-cirrhosis and the other groups, the higher values with lesser degrees of jaundice are more characteristic of the former. It appears from these data that values of 250 γ /24 hours, or higher, with total serum bilirubins less than 6.0 mg., as enclosed

FIG. 4. UCP AND TOTAL SERUM BILIRUBIN IN CASES OF BILIARY TRACT CANCER, COMMON DUCT CALCULUS, INFECTIOUS HEPATITIS, AND CIRRHOSIS

in the shaded area in Figure 4, are much more likely to be associated with hepatitis or cirrhosis, than with extrahepatic biliary obstruction.

Insofar as hepatitis is concerned, the determination of the UCP is of more value in detecting residual hepatic functional impairment at varying intervals after the disappearance of jaundice. In the present series 45 of 95 cases exhibited elevated values at varying intervals after disappearance of jaundice.

In Table VIII, the cases for which data were given in Table II, are subdivided as to whether the

increase or lack of increase of the UCP was associated with other abnormalities, either symptomatic, physical or laboratory in character. It is seen that the UCP was elevated in 11 instances (groups 2a and 2c) in which the other laboratory findings were normal. Five of these had significant symptoms or physical findings and six did not. The largest number of cases were in group 2b in which there were symptoms or physical findings together with other abnormal laboratory data. It should be noted that in a number of instances in this group the other laboratory abnormalities

TABLE VIII

Groups with presence or absence of symptoms,* physical findings,* or abnormal laboratory data	Case nos. (as in Table II)	Total
1. Symptoms or physical findings without abnormal laboratory findings	3, 19, 29, 35, 37, 59	6
2. UCP > 100 γ /24 hr. (abnormal)		
a. Without symptoms or abnormal physical findings and without other laboratory abnormalities	4, 11, 15, 38, 49, 61	6
b. With symptoms or physical findings and with other laboratory abnormalities	5, 6, 7, 9, 11, 12, 14, 16, 17, 18, 21, 22, 23, 27, 28, 30, 32, 33, 34, 40, 42, 43, 44, 45, 46, 48, 49, 51, 52, 53, 54, 56, 57, 59, 60, 62	36
c. With symptoms or physical findings but without other abnormal laboratory data	8, 10, 26, 31, 36	5
d. With other abnormal laboratory data, but without symptoms or physical findings	39, 41	2
3. UCP < 100 γ /24 hr. (normal), with other laboratory abnormalities, and with or without physical findings	13, 20, 24, 47, 50, 55	6

* Symptoms > I, liver enl. > 1 cm., liver tenderness + or greater (see key, Table II).

were isolated; thus, in Cases 7, 9, 18, 21, 23, 34, and 59, the only abnormality in addition to the excessive UCP, was an elevated urine Ehrlich reaction; while in Cases 33, 36, 43 and 53 the only other abnormality was in the serum bilirubin level.

It was of particular interest to compare the UCP and the bromsulfalein retention, especially in those cases in which other findings were borderline. As noted in Table II, the bromsulfalein test was carried out 53 times in 43 cases. The UCP value corresponding in time with these determinations, was significantly elevated ($> 100 \gamma/24$ hours) in 22 instances in which the bromsulfalein retention did not exceed 5 per cent; conversely, there was but one instance in which the opposite was true. This was Case 13 in Table II, in which the bromsulfalein retention was 8 per cent and the UCP 92 $\gamma/24$ hours. Insofar as the UCP and cephalin flocculation tests are concerned, inspection of Table II reveals a negative flocculation in a number of instances in which the UCP was significantly increased; none are found in which the reverse was true.

At present there is no way of determining whether residual functional impairment is synonymous with persistent activity of a virus hepatitis.

From a practical standpoint, at any rate, it is probably wise to advise caution as to unusual activity, strain, fatigue, alcohol, etc., at least until the evidence of residual impairment has disappeared. Case 49 in Table II is an example of this problem. Further data for this case are given in Figure 2 and Table VII. This individual was permitted to resume his normal occupation in spite of persistent elevation of the UCP, but at the same time he was enjoined to avoid undue fatigue, irregular hours of sleep and alcohol. One of the problems of the recovery state of hepatitis has been that the individual may complain of persistent weakness and fatigue even though the results of various liver function tests are normal or borderline. In a number of such instances included in the present study, the elevated urinary coproporphyrin gave indication of residual activity or impairment, and appeared to be correlated with the symptoms of fatigue, weakness or nervousness. Conversely, however, we have observed several individuals complaining of one or more of these symptoms yet having normal porphyrin values in addition to normal composite liver function studies. In such instances it has been impossible to decide with certainty whether the symptoms were on a psychic

FIG. 5. FREQUENCY DISTRIBUTION OF VALUES FOR URINARY COPROPORPHYRIN III IN CASES OF HEPATITIS, BILIARY TRACT CANCER, AND COMMON DUCT CALCULUS

basis or were in reality due to residual hepatic impairment. Additional studies, including exercise tolerance with relation to coproporphyrin excretion, are desirable in order to determine the degree of assistance one may expect from this determination.

From the present results it is evident that the increase in UCP in hepatitis and mechanical jaundice is due in the main to increased excretion of the type I isomer. Inspection of the data in Tables III, IV, V and VI, reveals, however, that in some instances the amount of type III isomer exceeds the normal upper limit of 34 γ /24 hours reported previously (14). In the hepatitis and infectious mononucleosis groups there are few of these and the excess is slight, probably within the limit of error of the differential precipitation method (12, 13). The two outstanding exceptions were cases in the calculous group which have already been referred to; one of these had a necrotic abscess with marked splenomegaly, and the other had miliary tuberculosis. In one additional instance (Case 13 in Table VI) an unexplained absolute increase of type III coproporphyrin is noted, comprising, however, but 17–18 per cent of the total UCP. In the cancer group, there are quite a number of cases having considerable excesses of type III isomer even though type I is clearly preponderant in each instance. Frequency distribution curves for the three groups are shown in Figure 5. Several cases, already discussed, have been omitted in the preparation of this figure, because of significant peculiarities believed to place them in separate categories. These cases are numbers 51 in Table II, 2 and 12 in Table VI. Figure 5 reveals the relative frequency of increased coproporphyrin III excretion in the cancer group. Nineteen of 39 cases in this group had values above 50 μ g. in 24 hours, while all of the 40 in the hepatitis group were below this level. Thus it is evident that the patients with cancer of the biliary tract or liver vary significantly in the composite, from the other groups, and especially from the hepatitis group, in respect to porphyrin metabolism. It appears that an absolute increase of the type III isomer greater than 50 γ /24-hour urine sample, favors the diagnosis of cancer rather than hepatitis, and is much more likely to be encountered with cancer than with calculus, in the presence of regurgitation jaundice. The reason for this difference is not

clear, but the possibility may be entertained of an endogenous chemical intoxication, from necrotic or abnormal cells. It is recognized too, that a constitutional factor cannot be excluded.

SUMMARY AND CONCLUSIONS

1. The total urinary coproporphyrin (UCP) is regularly increased above the upper limit of normal of 100 γ /24-hour urine sample, both in infectious hepatitis during the period of jaundice, and in cases of mechanical jaundice. The increase in cases of hepatitis often persists in some measure for considerable periods after the disappearance of jaundice and after the return to the normal range of conventional tests such as bromsulphalein retention and cephalin cholesterol flocculation. In certain instances the increase of the UCP has constituted the only objective evidence of residual hepatic functional impairment.

2. In cases of infectious mononucleosis the UCP is commonly increased, usually in association with other evidence of hepatic functional impairment.

3. Isomer analysis has shown that the increase in UCP in infectious hepatitis, infectious mononucleosis, and mechanical jaundice, is mainly due to the type I isomer. Certain exceptions are discussed and it is shown that in cases of cancer of the pancreas, bile ducts, or liver, the increased UCP, although preponderantly type I, includes an absolute increase of type III with relative frequency. This has not been observed to any significant degree in cases of infectious hepatitis, infectious mononucleosis, or uncomplicated calculous jaundice.

STUDIES ON VASOMOTOR TONE. I. THE EFFECT OF THE TETRAETHYLAMMONIUM ION ON THE PERIPHERAL BLOOD FLOW OF NORMAL SUBJECTS^{1, 2}

By SIBLEY W. HOOBLER, S. DONALD MALTON, H. THOMAS BALLANTINE, JR.,
SAUL COHEN, ROSALIE B. NELIGH, M. M. PEET, AND RICHARD H. LYONS³

(From the Departments of Medicine and Surgery, University of Michigan Medical School,
Ann Arbor, Mich.)

(Received for publication December 16, 1948)

The animal experiments of Acheson, Moe, and Pereira have shown that the tetraethylammonium ion is capable of relatively complete blockade of sympathetic and parasympathetic impulses at the autonomic ganglia (1-2). In the dog, the infusion of 20 mg. per kg. per hour will completely prevent the cardiac response to vagal stimulation, and the response of the nictitating membrane to preganglionic stimulation of the cervical sympathetic nerve (3). That the drug would also inhibit autonomic tone in man has been demonstrated in previous reports (4-7).

The purpose of the present investigation was 1. to study the effect of tetraethylammonium on blood flow in the extremities of normal and sympathectomized persons by the more quantitative plethysmographic technique; 2. to establish the extent of sympathetic vasomotor blockade produced by the drug; and 3. to compare its effect on peripheral blood flow with that of certain other vasodilating agents in common use.

METHODS

Peripheral blood flow was measured by means of a venous occlusion plethysmograph⁴ according to the technique described by Abramson (8). Collecting cuff pressures about 20-30 mm. of mercury below diastolic levels were selected and all subsequent determinations in any experiment were made at the same pressure in the collecting cuff.

¹ Presented before the National Meeting of the American Federation for Clinical Research at Chicago, Illinois, April 28, 1947.

² Supported by grants from Parke, Davis and Co., the Life Insurance Medical Research Fund, and the Division of Research Grants and Fellowships of the National Institute of Health, U. S. Public Health Service.

³ Present address: Syracuse University College of Medicine, Syracuse, N. Y.

⁴ We are indebted to Dr. I. Arthur Mirsky for the loan of the plethysmographs used in this investigation.

All blood flows were determined with the subject in the recumbent position, the room temperature at approximately 70° F and bath temperature at 32° C. Foot blood flow was determined with the subject horizontal and the plethysmograph at body level. Forearm and calf blood flows were determined after excluding return circulation from the hand and foot by means of tourniquets inflated to exceed arterial pressure for five minute periods during which consecutive blood flow measurements were made.

After the subject had rested 45 to 60 minutes, three to four series of blood flow determinations were performed. Each series consisted of five observations made at 30 second intervals in the resting state. During the experimental procedure blood flow was determined every 30 seconds for 10 to 15 minutes or until a maximum had apparently been reached. The average of at least five consecutive determinations just prior to the test procedure was designated as the *average resting blood flow* and of five consecutive determinations at the time of maximum increase as the *average maximal blood flow*.

In the sympathetic block experiments, resting blood flows were first obtained with the foot in the plethysmograph. It was then removed from the apparatus and 0.5 per cent metycaïne infiltrated in the region of L₁, L₂, and L₃ on one side according to the technique described by White and Smithwick (9), until paravertebral block had begun to take effect as judged by an increase in toe temperature with abolition of the temperature gradient between toe and thigh. The foot was then replaced as rapidly as possible in the plethysmograph and observations were repeated at frequent intervals until blood flow had fallen toward resting levels. That we were able to record the maximum flow after paravertebral block seemed apparent from the fact that the blood flow continued to increase for a while after the foot had been replaced in the plethysmograph and no decline appeared until after 15 to 30 minutes of observations.

Skin temperatures in the extremity opposite to the one enclosed in the plethysmograph were recorded by means of a Leeds-Northrup potentiometer, the thermocouples being held lightly in contact with the skin on the outside margin of the tip of the big toe or index finger, and on the anterior surface of the upper arm or thigh.

The normal subjects referred to in this report consisted of seven healthy male college students in whom the effects of varying dosage of tetraethylammonium,

other vasodilating procedures, and paravertebral block were compared. The remaining normal subjects consisted of 16 male and seven female patients ranging in age from 18 to 43, hospitalized for a variety of disorders but presenting no evidence suggesting the presence of any type of vascular disease.

OBSERVATIONS

1. Effect of tetraethylammonium on peripheral blood flow in normal subjects

In Table I are presented the effects of the intravenous injection of 500 mg. of tetraethylam-

500 mg. of tetraethylammonium chloride were given intravenously in all experiments.

* Blood flow values were calculated as described in the text. The value before TEA represents the average resting flow and that after TEA was the average maximal flow.

† Skin temperatures were determined on the extremity opposite to the one enclosed in the plethysmograph. Arm or thigh temperatures were not significantly altered by injection of TEA; consequently changes in gradient represent increases in toe or finger temperatures. Negative values indicate that digital temperatures exceeded skin temperatures of arm or thigh.

EFFECT OF INTRAVENOUS INJECTION OF TE-A-CL ON BLOOD FLOW IN FOOT

H.T. NORMAL 21 YR. OLD W. ♂

FIG. 1. TYPICAL RESPONSE OF NORMAL SUBJECT TO INTRAVENOUS INJECTION OF 500 MG. OF TETRAETHYLAMMONIUM CHLORIDE

monium chloride⁵ on peripheral blood flow and skin temperature. After the rapid intravenous injection of the drug, the blood flow in the foot always increased; that in the hands usually rose; while calf and forearm blood flows were unchanged or increased only slightly. In the few female sub-

jects studied there was a tendency for the drug to increase the blood flow in the foot and hand, more than in normal male subjects. The skin temperature gradient between toe and thigh was always reduced and often abolished while the temperature gradient between finger and forearm was less regularly affected. A typical response is shown in Figure 1. Foot volume usually increased after the administration of the drug and reached its

⁵ We are indebted to the Department of Clinical Investigation, Parke, Davis & Co., for the supply of "Etamon" used in these studies.

EFFECT OF INCREASING DOSES OF TEA ON BLOOD FLOW OF LEFT FOOT AS DETERMINED BY VENOUS OCCLUSION PLETHYSMOGRAPH

35 E. MC. NORMAL SUBJECT

FIG. 2. INCREASE IN BLOOD FLOW IN THE FOOT AFTER TETRAETHYLAMMONIUM IS APPROXIMATELY PROPORTIONAL TO THE DOSE ADMINISTERED

peak at the time of maximum flow. The systemic blood pressure did not fall markedly in any of the normotensive subjects studied, but pulse rate increased moderately after the drug. It was shown that tachycardia per se apparently had no effect on the plethysmographic measurement since comparable increases in pulse rate induced by the administration of atropine, 1 mg. intravenously to three normal subjects, had no significant effect on the foot blood flow.

2. Effects of dosage and route of administration

In three normal subjects it was demonstrated that greater and more prolonged increases in foot blood flow were obtained when 500 mg. rather than 300 mg. of the drug were given intravenously. A 500 mg. dose was not exceeded except in one

case in which 700 mg. produced a greater rise in blood flow than 500 mg. (Figure 2). In one subject the intramuscular injection of 20 mg. per kg. resulted in a more prolonged but no greater rise in blood flow than a 500 mg. dose given intravenously.

3. Effect of tetraethylammonium on reflex vasomotor changes

Following the injection of tetraethylammonium, the reflex vasoconstrictor response to pinprick and mental arithmetic was reduced or absent. Respiratory and other rhythmic changes in limb volume were reduced (Figure 3). Reflex vasoconstriction induced by suddenly immersing an opposite extremity in ice water was likewise obliterated by tetraethylammonium (Figure 4).

REFLEX CHANGES IN LIMB VOLUME BEFORE AND AFTER TEACI

FIG. 3. REDUCTION IN REFLEX CHANGES IN LIMB VOLUME AFTER AUTONOMIC BLOCKADE WITH TETRAETHYLAMMONIUM

The upper tracing is a control plethysmographic observation. The lower record was obtained eight minutes after the administration of 500 mg. of tetraethylammonium chloride intravenously. At 1 and 2 a painful stimulus (pin prick) was applied. At 3 the patient was given a problem in mental arithmetic to perform.

Note the reduction in rhythmic volume changes and in the response to various stimuli after autonomic block.

FIG. 4. BLOCKADE OF REFLEX VASOCONSTRICTION TO COLD STIMULUS AFTER AMMONIUM

Representative inflow curves in the hand have been selected from the plethysmographic tracings of a normal subject before and after 500 mg. of tetraethylammonium chloride intravenously. Numbers 2, 5, and 8 were recorded 60 seconds after immersion of the opposite hand in ice water. The tracings on the left and right represent inflow curves one minute before and $1\frac{1}{2}$ minutes after cessation of the ice stimulus.

It will be noted that the reflex vasoconstriction apparent in the first series of tracings was abolished three minutes after tetraethylammonium chloride and had begun to return 15 minutes after the injection.

1. Effect of tetraethylammonium compared to that of other vasodilating procedures

(a) Heat

In seven normal subjects vasomotor tone was reduced by heating the body and three extremities under an electric blanket for 30 to 45 minutes until

marked diaphoresis occurred and no further increases in blood flow in the foot could be produced. The increases obtained by this procedure showed considerably greater variation and were somewhat less than after a single injection of 500 mg. of tetraethylammonium (Figure 5). When the drug

was given at the point of maximum reflex vasodilatation, only minimal increases in blood flow were observed.

(b) Vasodilating drugs

Observations on the effect of nicotinic acid, papaverine, aminophyllin, and nitroglycerin on foot blood flow were made in several normal male subjects in whom the effects of tetraethylammonium had also been studied. These drugs had far less effect than did tetraethylammonium given to the same subjects (Figure 5).

(c) Lumbar paravertebral block

In four instances lumbar paravertebral block was induced with metycaine before or after the response of the vascular bed in the extremity to tetraethylammonium had been tested. The block was usually slightly more than twice as effective as

tetraethylammonium in increasing blood flow to the foot, and the hyperemia lasted from three to four times as long (Figures 5, 6). In cases where block appeared incomplete, as judged by a delayed or incomplete rise in toe temperature before placing the foot in the plethysmograph, and by a less than usual increase in blood flow, injection of tetraethylammonium resulted in further vasodilatation. Also when sympathetic block had begun to wear off, as manifested by a decline in blood flow in the foot, an increase in blood flow could be obtained by an injection of tetraethylammonium.

5. Effect of tetraethylammonium on the sympathectomized extremity

In one patient with early Buerger's Disease, tetraethylammonium increased blood flow in the foot from 3 cc. to 10 cc. per 100 cc. of limb volume per minute. After lumbar sympathectomy blood

FIG. 5

Length of the solid bars indicates the increase in blood flow after the various procedures described in the left-hand margin of the figure. The increase in foot blood flow in centimeters per 100 cc. foot volume per minute is expressed numerically beside each bar. Experiments performed in the same individual on different days are arranged in vertical columns beneath the subject's initials.

It will be observed that paravertebral block was the most effective vasodilating procedure, that tetraethylammonium chloride and reflex body heating produced about one-half as great an increase in foot blood flow and that certain common vasodilator drugs were considerably less effective.

FIG. 6. COMPARATIVE EFFECT OF TETRAETHYLAMMONIUM AND OF LUMBAR PARAVERTEBRAL BLOCK WITH METYCAIN ON FOOT BLOOD FLOW IN NORMAL SUBJECT

Note that at height of sympathetic block administration of tetraethylammonium produced no significant change in blood flow but that after the effects of the metycain had worn off, tetraethylammonium produced vasodilatation of somewhat lesser magnitude and duration.

flow averaged 5 cc. per minute but injection of the drug was now without vasodilator effect (Figure 7). On 12 other occasions we have observed that sympathectomy has abolished the vasodilator response to tetraethylammonium. These observations have been made four times with respect to blood flow in the hand and eight times with respect to blood flow in the foot, and as early as the second day after operation and as late as the ninth month following sympathectomy.

DISCUSSION

Tetraethylammonium significantly increased blood flow to the foot in every normal subject studied; it produced vasodilatation in the hand in seven of eight instances; while circulation in the forearm and calf increased only slightly in most of the subjects. These plethysmographic observations correspond to those of Slaughter, Brown, and Wakim (10) who used an air displacement plethysmograph and measured circulatory changes in the hand and forearm or foot and calf.

The increases in temperature following tetraethylammonium provide confirmatory evidence of the peripheral vasodilator action of the drug. This occurred regularly in the toes and frequently in the fingers. Elevation in skin temperature in the extremities of subjects with vasospastic peripheral vascular disease has been reported previously (4-7). On the other hand, Boyd *et al.* (11), and DeBakey *et al.* (12) have found elevations of the digital temperature to occur less consistently both in the normal and in the subject with peripheral vascular disease. We are unable to explain these discrepancies but we believe that the plethysmographic observations herewith reported provide convincing evidence of the vasodilator action of the drug, at least so far as the blood flow in the entire hand or foot are concerned.

Since tetraethylammonium no longer produces vasodilatation after an extremity has been sympathectomized, it follows that the drug acts by altering sympathetic tone and not by any direct vasodilator action on the blood vessels. This conclusion

is further supported by the observations that the vasodilator response is reduced or abolished when vasoconstrictor tone is reduced by body heating and by the observation that vasoconstrictor reflexes following pain, cold, and mental activity are reduced or abolished during the period of action of the drug. Finally, the less marked increases in blood flow in the forearm or calf following tetraethylammonium can be readily explained by the relative lack of vasomotor tone to these vascular areas (8). Our clinical findings, therefore, are not at variance with the results of investigations performed in animals (1, 2). While it is impossible to prove the ganglionic site of action in the human subject as in the animal, it seems most likely that blockade of sympathetic impulses occurs in this location.

If it may be assumed from our studies that lumbar paravertebral block produced complete inhibition of vasomotor tone in the foot, the maximum blood flow under these conditions averaged 17.6 cc. per 100 cc. of foot volume in four normal

subjects. This figure may be compared to an average maximum flow of 9.9 cc. after administration of 500 mg. of tetraethylammonium. It would appear that the increase in blood flow after this drug represented about one-half the possible increase had a complete chemical block been established. In larger doses it is probable that a more complete blockade could have been achieved since in one subject the response to the injection of 700 mg. of the drug was greater than after the administration of 500 mg. and approximated the degree of vasodilatation to be expected from complete sympathetic block. However, we do not believe that in the average human subject more than 500 mg. can be administered with safety by the intravenous route. The failure to achieve greater inhibition of sympathetic tone was somewhat unexpected since the autonomic nervous system of the dog can apparently be blocked almost completely to pre-ganglionic faradic stimulation for a brief interval by doses of 4 to 8 mg. per kg. (3). If this were applied to a human subject weighing 60 kg., it would

FIG. 7. EFFECT OF TETRAETHYLAMMONIUM ON BLOOD FLOW BEFORE AND AFTER SYMPATHECTOMY

Vasodilator response to tetraethylammonium occurring prior to sympathectomy in a patient with early Buerger's Disease was abolished by the operation. Failure to increase blood flow in sympathectomized extremity indicates that the drug has no direct vasodilator action in this dosage.

The slight decline in blood flow after tetraethylammonium on fifth post-operative day was probably the result of parallel decline in blood pressure. It will be noted that body heating likewise failed to produce vasodilatation on the fifth day following sympathectomy.

mean that 480 mg. given intravenously should have produced a temporary but relatively complete blockade.

Gibbon and Landis (13) and Coller and Mad-dock (14) have utilized reflex heat vasodilatation as a means of inhibiting sympathetic vasomotor tone. The degree of vasodilatation achieved was measured by alterations in the digital temperature. The extent of the peripheral vasodilatation, as measured in the plethysmograph, which could be induced by prolonged body heating in five normal subjects was more variable and of a lesser magnitude than the response to 500 mg. of tetraethylammonium. Despite the frequent obliteration of the temperature gradient between toe and thigh following both these procedures, the increases in blood flow were far less than after paravertebral sympathetic block. It would appear from these observations that reflex heat vasodilatation likewise does not produce a complete release of vasomotor tone and the abolition of a skin temperature gradient does not necessarily mean that a complete sympathetic blockade has been achieved.

While we made no extensive comparative studies of the effects of various vasodilator drugs on blood flow in the foot, a few observations utilizing the plethysmographic technique have convinced us that, at least in the normal subject, measures involving an inhibition in vasoconstrictor tone result in significantly greater increases in blood flow than do those vasodilating agents which act on the peripheral vessels directly. The increase in blood flow following papaverine, nitrites, nicotinic acid, and aminophyllin given intravenously was far less than that seen after lumbar sympathetic block, tetraethylammonium, or reflex heat vasodilatation. The extensive studies of Abramson and his associates (8) on the effect of various vasodilator drugs and of Gubner *et al.* (15) on the effects of glycine would suggest that increases in the peripheral blood flow of the magnitude which followed tetraethylammonium are most uncommon.

CONCLUSIONS

1. Tetraethylammonium in doses of 500 mg. intravenously produces an average seven-fold increase in foot blood flow, a four-fold increase in hand blood flow, and slight increases in forearm

and calf blood flows in the normal subject as measured by the venous occlusion plethysmograph. Digital skin temperatures are increased and the temperature gradient between thigh and toe and forearm and finger are usually abolished or greatly reduced.

2. The drug does not produce vasodilatation in the sympathectomized extremity. Its vasodilator action is therefore the result of the inhibition of sympathetic vasoconstrictor tone.

3. Sympathetic blockade is probably incomplete with the usual doses of tetraethylammonium tolerated by the human subject. The vasodilatation in the foot, which follows 500 mg. of the drug, is about 50 per cent of that observed after lumbar paravertebral block.

4. In the foot of the normal subject, the increase in blood flow is of much greater magnitude after tetraethylammonium than after aminophyllin, papaverine, nicotinic acid, and nitroglycerin and is slightly greater than the vasodilatation following prolonged body heating.

THE EFFECT OF ANOXIC ANOXIA ON THE HUMAN KIDNEY¹

By EUGENE Y. BERGER, MORTON GALDSTON, AND SEYMOUR A. HORWITZ
WITH THE TECHNICAL ASSISTANCE OF ROSLYN JACKENTHAL
AND MARILYN PRUSS

(From the Research Service, Third New York University Medical Division, Goldwater Memorial Hospital, Welfare Island, New York and the Department of Medicine, New York University College of Medicine, New York, New York)

(Received for publication December 18, 1948)

Congestive heart failure is associated with reduction of renal blood flow and retention of salt and water. The possibility has been raised that these changes may result from the concomitant renal anoxia (1, 2). The present studies are concerned with the effect of anoxia on the human kidney under situations of normal cardiovascular dynamics.

METHODS

In subjects with normal cardiovascular and respiratory systems, an arterial blood oxygen tension of approximately 50 mm. Hg was induced by the inhalation of 14 per cent oxygen. This concentration of oxygen was selected in order to induce a maximum degree of anoxia compatible with minimal changes in cardiovascular and respiratory dynamics (3). Observations of discrete renal functions were then made in these subjects and compared with renal functions while breathing room air. Observations were also conducted on emphysematous individuals who had arterial blood oxygen tensions of approximately 50 mm. Hg while breathing room air and observations were repeated while breathing 100 per cent oxygen. In the latter cases, periods while breathing room air were considered to be anoxic periods and periods while breathing 100 per cent oxygen were considered control periods. In all cases, 20 to 45 minutes were allowed for equilibration following a change of oxygen concentration in respired air.

Glomerular filtration rate was measured as the inulin clearance and renal plasma flow as *p*-aminohippurate clearance, following the principles outlined by Smith (4). An intravenous infusion of saline containing inulin and sodium *p*-aminohippurate was administered at a rate of 3 ml./min. subsequent to an appropriate priming dose. Urine was collected in periods of 15 to 30 minutes through an indwelling multi-eyed catheter. At the end of each period the bladder was rinsed with distilled water. Urine samples for measurement of pH were collected and kept under oil. At the mid-point of each urine collection period, blood was drawn anaerobically from the femoral

artery through an indwelling needle. Heparin was used as an anticoagulant. The renal data in the tables represent the means of three collection periods.

Since the inulin and *p*-aminohippurate were administered in an infusion, the addition of a small amount of normal saline to the circulating volume (500 ml. over 3 hours) might be responsible for the observed changes in electrolyte excretion. To obviate this factor, the time relationship of the control to anoxic periods was varied. In CH, LS, LB, MH, and MS, the control periods preceded the anoxic periods. In KN, DV, and NG, the control periods followed the anoxic periods. MS was further studied to follow his return to the control levels.

Inulin was measured in urine and plasma by Harrison's modification (5) of Alving's method (6). *p*-Aminohippurate was measured in diluted urine and trichloroacetic acid filtrates of plasma by the Bratton-Marshall reaction (7). Sodium and potassium were determined with an internal standard flame photometer (8). Chloride was determined according to Wilson and Ball (9); phosphorus according to Fiske and SubbaRow (10); ammonia according to Summerson's modification of the Van Slyke and Cullen procedure (11); pH with a Leeds and Northrup pH meter; urinary protein was determined by the micro-Kjeldahl technique using a trichloroacetic acid precipitation.

Expired air was collected in a Tissot spirometer which recorded respiratory rate and volume. The mouth piece and nose clip were kept on the subject throughout the procedure except for a few minutes rest prior to a change in oxygen concentration in the inspired air. Arterial blood oxygen and carbon dioxide contents were determined by the method of Van Slyke and Neill (12), and tensions by the direct method of Riley (13). Respiratory gases were analyzed in a Haldane-Henderson apparatus and micro-Scholander gas analyzer (14).

The pulse rate and brachio-arterial blood pressure were recorded at five-minute intervals throughout any particular procedure. Mean arterial blood pressure levels were calculated by adding a third of the systolic and diastolic difference to the diastolic pressure.

With a view to minimizing the problem of anxiety, prior to the day of experiment the subjects were catheterized and were acclimated to breathing through a Tissot spirometer. The subject was not informed of changes in oxygen concentration during the experiment and gave no indication of having noticed the change.

¹ This investigation has been aided by grants from the Josiah Macy Jr. Foundation and the Division of Research Grants and Fellowships of the National Institute of Health, U. S. Public Health Service.

OBSERVATIONS

There were slight alterations in respiration and circulation during inhalation of 14 and 100 per cent oxygen (Table I). The changes in respiration were all within the error of measurement. The average pulse rate did not change significantly in four observations while it rose 8 to 14 beats during anoxia in the other five. The average mean blood pressure during the anoxic periods was not different from that of the control except in one instance when it rose 13 mm. Hg during anoxia.

Renal plasma flow did not decrease during the anoxic periods. On the contrary, there was a tendency for it to increase. In observations in individuals with normal pulmonary function, three comparisons exhibited no appreciable change in renal plasma flow and four increased 13 to 20 per cent. In the two subjects with pulmonary emphysema, the administration of 100 per cent oxygen induced a fall in renal plasma flow; considering periods of breathing room air as the anoxic periods there was an increase in renal plasma flow of 29 per cent in each subject during anoxia. The filtration rate did not change appreciably during anoxia in four observations, increased 9 to 23 per cent in four, and decreased 19 per cent in one.

The interpretation of *p*-aminohippurate clearance as a measure of renal plasma flow is based on its almost complete extraction by the kidney. Under normal situations this extraction is at a maximum. A decrease in *p*-aminohippurate clear-

ance during anoxia would be difficult to interpret in terms of renal plasma flow if the anoxia altered its extraction. However, the observed clearances increased and a change in this direction can be interpreted as an increase in effective renal plasma flow.

In the five comparisons where a change in pulse rate did occur, those which evidenced the greatest change in pulse rate did not have the greatest change in renal plasma flow. Since it has been observed that the increase in cardiac output which occurs during inhalation of anoxic gas mixtures results from an increase in pulse rate rather than stroke volume (15, 16), the observed changes in renal plasma flow are not considered to reflect changes in cardiac output.

There was an invariable and frequently marked increase in the rate of sodium and chloride excretion during anoxia (Table II). Sodium increased from a mean excretion of 162 μ Eq./min. to 256 μ Eq./min. Chloride increased from a mean excretion of 161 μ Eq./min. to 245 μ Eq./min. The urine flow tended to increase during anoxia presumably in consequence of the increased concentration of sodium and chloride in the urine. The magnitude of change in salt and water excretion exhibited little if any correlation with the magnitude of change in filtration rate or renal plasma flow.

Other electrolyte changes which occurred during anoxia were not as marked as those of sodium and

chloride. Urinary pH shifted to higher values in all observations except one but this subject had a control value of pH 7.6. Ammonia production decreased in all but one observation. Potassium excretion increased in all but two observations. Proteinuria did not develop during anoxic periods.

The phosphorus excretion usually increased as the experiment progressed irrespective of changes in blood oxygen tension.

DISCUSSION

A lowered arterial blood oxygen tension in subjects with normal cardiovascular function induced a marked increase in the renal excretion of sodium and chloride. In no instance did renal plasma flow decrease during anoxia. It would appear, therefore, that anoxic anoxia per se is not the cause of the retention of salt and water nor in the reduction of renal plasma flow observed in congestive heart failure.

If arterial blood oxygen tension is lowered in normal subjects, renal plasma flow and sodium and chloride excretion increase. If arterial oxygen tension is raised in anoxic emphysematous subjects, renal plasma flow and the excretion of sodium and chloride decrease.

The duration of anoxia was only one to two hours in the normal individuals in the investigation, but the emphysematous individuals had maintained a status of anoxic anoxia over a period of years. It is of interest that even in the latter subjects the effect of chronic anoxic anoxia on the kidney was readily altered.

The effect of lowering arterial blood oxygen tension beyond 50 mm. Hg was not investigated as complicating changes in cardiovascular and pulmonary dynamics were likely to be introduced. It is to be noted that in congestive heart failure and in disease states associated with arterial oxygen unsaturation, oxygen tensions seldom fall below 50 mm. Hg.

In the normal subjects during anoxia, oxygen tension in inspired air was 106 mm. Hg. McDonald and Kelley (17) investigated renal plasma flow and filtration rate in dogs at simulated altitudes where oxygen tensions in inspired air were 79.4 and 61.6 mm. Hg. They found renal plasma flow to increase at higher altitudes, observations which are in accord with those reported here.

The increase in urine flow in these studies confirms previous work in the rat (18), dog (19), and man (20) where polyuria has been observed at higher altitudes. Burrill *et al.* (21) reported a rise in the excretion of sodium and chloride during one hour exposures of adult males to simulated altitudes of 18,000 feet. Interestingly enough, they observed a compensatory retention of these ions following the exposure so that the 24 hour excretion was not altered.

The normal dog excretes excessive amounts of sodium and chloride when exposed to 10.5 per cent oxygen for 24 hours whereas the adrenalectomized animal fails to do so (22). Thorn (23) found rats treated with adrenal cortical extract survived longer at higher altitudes than untreated animals. These facts suggest the possibility that the changes in sodium and chloride observed in the present study may be in some way related to altered adrenal metabolism at low oxygen tensions. The behavior of potassium did not, however, conform to this hypothesis.

SUMMARY

Renal plasma flow in man did not decrease under situations of anoxia where arterial oxygen tension was lowered to about 50 mm. Hg. The most pronounced effect of lowered oxygen tension on renal tissue was the increased excretion of sodium and chloride. Anoxic anoxia alone, therefore, does not appear to be the cause of the reduction of renal plasma flow nor the retention of salt and water observed in congestive heart failure.

ACKNOWLEDGMENTS

The authors are indebted to Dr. Irving Leff and Dr. Herta Spencer for their valuable assistance in these studies.

DETERMINATION OF ADRENERGIC AND CHOLINERGIC SUBSTANCES IN THE BLOOD OF MAN¹

BY MARC J. MUSSER AND ELIZABETH A. GRIMM

(From the Department of Internal Medicine, University of Wisconsin Medical School, Madison)

(Received for publication August 2, 1948)

Much has been written about the clinical manifestations which indicate disturbances in function of the autonomic nervous system in numerous disease processes. Various clinical signs are identified with orthosympathetic or parasympathetic predominance. Autonomic drugs are used diagnostically and therapeutically, and surgical procedures have been devised which temporarily or permanently interrupt the neurogenic influences of this system upon the various parts of the body. Yet, consistently lacking have been objective tests which might indicate the nature or degree of existing autonomic disturbances. The availability of such tests would materially facilitate an evaluation of the importance of the autonomic nervous system in such diseases as thyrotoxicosis, peptic ulcer, hypertension, bronchial asthma, and a large number of the neuropsychiatric disorders.

Current concepts of the mediation of autonomic nervous system effects include humoral mechanisms. Investigation of the latter was the object of this study.

The well known responses of isolated rabbit intestine to epinephrine and acetylcholine have made possible its use as a method of identification of these substances in various solutions, including blood. The marked sensitivity and the relative specificity of the adrenergic response (1) as well as the simplicity of the method make it the best of the biologic tests for this substance so far developed. The cholinergic response is equally sensitive but much less specific since many substances besides acetylcholine cause an increase in the tone and contraction of the gut by their action upon the parasympathetic ganglion cells in the walls of the muscle (2, 3).

Isolated rabbit duodenum was used by Milhorat, Small, Doty and Bartels (4) and Diethelm, Doty and Milhorat (5) to assay the blood of patients with emotional disturbances for adrenergic

and cholinergic substances. They concluded that anxiety, resentment, and anger appeared to be accompanied by adrenergic factors in the blood while tension and possibly fear were accompanied by cholinergic factors. Furthermore their results indicated no essential difference between normal and psychopathological emotions except in the intensity of adrenergic and cholinergic responses.

If it is true that adrenergic and cholinergic substances can be demonstrated in the blood of healthy individuals, one might expect qualitative or quantitative differences of these substances in patients with diseases which are accompanied by evidence of disturbed autonomic function. In addition, autonomic nervous system surgery might be expected to alter these circulating substances, especially if the humoral mechanism of autonomic effect is significant. Two circumstances are recognized, however: 1. the human organism is capable of maintaining a remarkably fine humoral balance under normal and some abnormal conditions, and 2. humoral influences are effected not only by the amount of a circulating material but also by the ability of a tissue to respond to it.

PROCEDURE

Rabbits were killed by the injection of air into an ear vein. The intestine was cut at the pylorus and about 10 cm. of the duodenum removed. After thorough washing a piece 1.5 cm. in length was placed in 200 cc. of Ringer-Tyrode solution maintained at a temperature of 36° to 38° C by a thermostatically controlled water bath. The solution was stirred gently by a stream of air. A recording lever was attached to one end of the muscle and the contractions were recorded on a kymograph. The sensitivity of the preparation to epinephrine and acetylcholine was determined by the addition to the solution of these drugs in varying amounts by means of long screw-controlled pipettes. An amount was chosen which would give consistently a decisive but not prolonged effect. For acetylcholine this meant a concentration of 1:200,000,000 to 1:50,000,000; for epinephrine it varied from 1:100,000,000 to 1:16,000,000. The acetylcholine was added first, followed by the epinephrine, after which the preparation was washed and resuspended in fresh Ringer-

¹ This study was made possible by a grant from the S. G. Heath Fund.

FIG. 1

1. Blood from normal male added—negative response.
2. 0.15 cc. ACH, 1:10,000 added.
3. 0.12 cc. EPH, 1:10,000 added.

Tyrode solution. If epinephrine was added to a preparation repeatedly without changing the Ringer-Tyrode solution, the sensitivity of the tissue decreased with each successive application until finally the contractions continued with the usual amplitude and frequency despite the addition of the drug. If, however, the tissue was then washed and resuspended in fresh solution, it again responded with its original sensitivity. This change in sensitivity with repeated applications of the drug has been noted by Hoskins (1) and Bernheim (6) although neither offered an explanation for the phenomenon.

When the response of the preparation to known solutions of epinephrine and acetylcholine was determined, blood specimens were tested as follows. The blood was drawn from the patient's median cubital vein into a syringe moistened with heparin and within three to 10 minutes was added to the fresh Ringer-Tyrode solution in which the muscle was suspended. After the effect of the blood was recorded, known amounts of epinephrine and acetylcholine were added to this solution to test the tissue sensitivity. Thereafter, the tissue was again washed and suspended in fresh Ringer-Tyrode preparatory for

another test. It was possible to use most muscle preparations for four to six hours with no significant change in their response to the known amounts of epinephrine and acetylcholine. In some instances, in addition to the whole blood sample, blood was centrifuged, separated, and the plasma and cells tested separately. In these latter experiments, there was an interval of 35 to 45 minutes between the drawing of the blood and the addition of the separate constituents. Test solutions of varying concentrations of pitressin were also used.

FIG. 3

1. Blood from normal male added—CHO (2) response.
2. 0.04 cc. ACH, 1:10,000 added.
3. 0.04 cc. EPH, 1:10,000 added.

FIG. 4

1. Blood from hypertensive female added—prolonged CHO effect.
2. 0.04 cc. ACH, 1:10,000 added.
3. 0.04 cc. EPH, 1:10,000 added.

Responses were recorded as follows: "cholinergic" (CHO), meaning an increase in muscle tone and amplitude of contraction; "adrenergic" (ADR), meaning a decrease in tone and amplitude of contraction; "Negative" (NEG), if no change was noted; and "indeterminate" (I), when the change was bizarre and neither definitely cholinergic nor adrenergic. The degree of response was recorded as 1. (less than), 2. (equal to), and 3. (more than) the response of the tissue to known amounts of acetylcholine and epinephrine.

FIG. 2

1. Blood from normal male added—indeterminate response.
2. 0.02 cc. ACH, 1:10,000 added.
3. 0.02 cc. EPH, 1:10,000 added.

FIG. 5

1. Blood from male with ulcerative colitis added—prolonged ADR effect.
2. 0.04 cc. ACH, 1:10,000 added.
3. 0.08 cc. EPH, 1:10,000 added.

Responses which did not occur within 25 seconds after the addition of the blood were considered "delayed" (D), and those persisting more than five minutes were considered "prolonged" (P). In no instances did responses to known amounts of the pure drugs persist longer than one minute.

In some instances the response was at first cholinergic and then adrenergic. This is so indicated by an arrow in the tables of results. Examples of the various responses are shown in Figures 1 through 7.

The types of cases studied are listed in Table I. Controls consisted of members of the hospital staff and were engaged in essentially the same duties. All were well known and were felt to be emotionally stable. Each was questioned regarding the existence of any particular or excessive emotional reaction existing at the time the blood sample was taken. Patients were selected as typical and clear-cut examples of the illnesses from which they suffered. Those with emotional disturbances had chronic anxiety tension reactions which varied but little from day to day. In each instance, at the time of testing, none was experiencing any acute or unusual emotional reaction.

whole and in the individual subject. This is especially apparent in the morning and afternoon samples tested on consecutive days. Types of response could not be correlated with any particular environmental situation, physical state, or minor emotional reaction arising during the course of the subject's daily hospital duties.

No consistent responses were observed when whole blood, plasma, or cells were tested separately (Table IV and Figure 7). Cannon (7) reported that serum and whole blood would cause the same shortening when added to the muscle strip. Mil-

horat *et al.* (4) stated that the substances in the blood producing the effects they described were labile and would disappear if the blood was allowed to stand 15 to 20 minutes after being drawn. Cannon (7) stated that blood from excited animals which produced inhibition of an intestinal strip lost this power upon standing in the cold for 24 hours or when kept warm and agitated with bubbling oxygen for two to three hours. As can be seen in Table IV, in only two instances did the addition of plasma fail to show an effect upon the muscle even though it was added as long as 30 to 45 minutes after withdrawal of the blood from the subject.

The blood from patients with chronic anxiety tension reactions (Table V) likewise showed considerable irregularity of effect. Morning and afternoon variation was marked; there was no relationship between the type and intensity of the muscle response and the severity of the emotional disorder; and in general, the intensity of the muscle response was less than the response to the solutions of known amounts of acetylcholine and epinephrine. As pointed out above, none of these patients was tested during acute emotional reactions. All exhibited chronic anxiety over their somatic symptoms and existing environmental problems, and were prone to develop excessive tension in response to stress. In the majority of them, psychiatric investigation had demonstrated the presence of deep-seated and repressed resentment and/or fear. With such mixtures of emotional reactions, individually accompanied by adrenergic or cholinergic factors (5), such variability of results as were observed was not unexpected. It is important to note that as a group they produced effects entirely similar to the controls.

One patient with a severe involutional melancholia was tested while she was extremely agitated, fearful, and protesting vehemently against the venipuncture. On one occasion (morning) her blood was adrenergic, on the other (afternoon) it was cholinergic. In each instance, it was impossible to determine the predominate emotional reaction.

Blood of patients suffering from peptic ulcer and ulcerative colitis, diseases in which parasympathetic predominance has been felt to exist, showed adrenergic effects in the majority of tests (Table V).

Blood from bronchial asthma patients was predominately adrenergic in effect, regardless of the severity of symptoms at the time of specimen withdrawal. The type of muscle response—delayed and prolonged—was more consistent in this group than in any other studied. No explanation for this was apparent. All blood samples were drawn at least two hours after any medication. One patient (No. 3), who in addition to asthma had a severe anxiety tension state, could not tolerate epinephrine.

Results from thyrotoxic patients were equally as irregular as the control studies. Degree of toxicity did not seem to be a factor.

Likewise there was considerable variability in the effects of blood taken from patients suffering from essential hypertension. In three cases (Nos. 36, 37, and 38) samples drawn the day before and seven days after thoracolumbar sympathectomy were similarly inconsistent.

In all of the experiments, the response of the muscle strip to blood was frequently prolonged and in this respect differed considerably from the response to solutions of acetylcholine and epinephrine.

DISCUSSION

The data obtained allow for no conclusions regarding the status of the autonomic nervous sys-

tem in the several diseases studied. The most that can be said is that with the method used there is no significant difference in the effects upon isolated rabbit duodenum of blood taken from normal persons and patients suffering from certain types of chronic emotional disturbances, ulcerative colitis, peptic ulcer, bronchial asthma, thyrotoxicosis, and essential hypertension. It remains entirely

possible that in these and other diseases, substances may be present in the blood which are the result of, or are quantitatively altered by, disturbances in autonomic nervous system function. Should such substances be present, it must be concluded that the method under investigation is not capable of consistently demonstrating them.

Aside from the irregularity and inconsistency

FIG. 8

1. 0.02 cc. pitressin diluted 1:1000—no effect.
2. 0.10 cc. pitressin diluted 1:1000—no effect.
3. 0.02 cc. pitressin undiluted (20 units/cc.)—ADR effect followed by CHO effect.
4. New Ringer-Tyrode solution.
5. 0.02 cc. pitressin undiluted—same effect as before.

of the results for which no satisfactory explanation is apparent, the very nature of the responses of the muscle to blood was sometimes difficult to interpret. In numerous tests, after the addition of the blood sample, the first effect noted was a transient increase in muscle tone and amplitude of contraction. This was followed by a decrease in tone and amplitude which might be marked and prolonged. This type of response might be interpreted as evidence of the existence of both cholinergic and adrenergic substances in the blood and in our results has been indicated as such.

However, Hoskins (8) observed that the application of epinephrine in a dilution subminimal to that needed to produce a characteristic inhibition of muscular activity would frequently increase the activity of the tissue and often cause an increase in tonus. Thus both types of muscle response might be produced by an adrenergic factor. In our experiments, especially in the initial mixing of blood with the Ringer-Tyrode solution in which the muscle was suspended, some transitory variation in dilution might possibly have occurred and could not have been avoided. It has also been shown that epinephrine appears to have the ability of increasing the synthesis of acetylcholine (9) and of inhibiting cholinesterase activity (10, 11). Presumably, under the proper circumstances, this also could result in an alteration of characteristic muscle response.

Reference has been made earlier to the ability of many substances besides acetylcholine to increase

the tone and amplitude of contraction of the gut. The response of the duodenal muscle strip to pitressin (Figure 8) is of interest in this regard. Actually, there is considerable doubt whether acetylcholine is ever present in circulating blood under normal circumstances. Existing in the tissues in a physiologically inactive form, it is activated by nerve impulses but almost immediately destroyed *in situ* by the enzyme, cholinesterase, which is a normal constituent in blood (12, 13). Dale (13) has shown that only in the presence of eserine does acetylcholine appear in a perfusion fluid. Thus it is most unlikely that the "cholinergic" effects noted in this and other similar experiments were due to acetylcholine.

The frequency with which blood caused effects quite different from the solutions of epinephrine and acetylcholine, the marked irregularity and inconsistency of the results, and the uncertainty of the nature of the substances producing the "adrenergic" and "cholinergic" effects raise considerable question as to the significance of the response of isolated rabbit duodenum to blood. It becomes apparent that this method is not a satisfactory means of testing for the presence of truly adrenergic substances in the blood.

CONCLUSIONS

1. No significant differences were observed in the responses of isolated rabbit intestine to blood from normal, psychoneurotic, and organically ill

subjects. Marked variability and irregularity of responses were present throughout.

2. Repeated studies on the same subjects showed diurnal as well as day to day variations in effect. These variations did not correlate with the existing emotional status, the influence of environmental factors, or the type or severity of illness.

3. The irregularity and inconsistency of the results and the uncertainty of the exact nature of the substances in blood having what have been thought to be adrenergic and cholinergic effects upon muscle, cause us to feel that the response of isolated rabbit duodenum to blood is not a satisfactory method of studying autonomic nervous system function.

CONCENTRATION-TIME COURSE IN THE PLASMA OF MAN OF RADIOMERCURY INTRODUCED AS A MERCURIAL DIURETIC¹

By S. A. THREEFOOT, C. T. RAY, G. E. BURCH, J. A. CRONVICH,²
J. P. MILNOR,³ W. OVERMAN, AND W. GORDON

(From the Department of Medicine, Tulane University School of Medicine, and Charity
Hospital of Louisiana, New Orleans)

(Received for publication December 20, 1948)

INTRODUCTION

During the course of investigations into the mechanism of congestive heart failure and other states of edema, it became evident that there was need for further understanding of the pharmacodynamics of the mercurial diuretics, including their distribution, mechanism of action, and elimination. Studies based upon chemical methods of analysis are limited because of the minute concentrations of the mercurial compounds present in the body fluids and tissues and the number of samples which can be analyzed in a given time. The use of the tracer technic made possible the extension of these studies to smaller quantities and to a greater number of determinations.

This presentation is directed at a better definition of the concentration-time course of mercury intravenously injected as a diuretic into the circulating plasma of man. A mercurial diuretic (Mercuryhydrin⁴) labeled with radioactive mercury⁵ was employed in the tracer studies. It is well to realize that it is the mercury which is being traced and not the molecule of the diuretic.

⁴ The sodium salt of methoxyoximercuripropylsuccinylurea with theophylline, prepared with radiomercury in this laboratory by Messrs. Harold Krahnke, Darwin Kaestner and Edwin Sprengler through the courtesy of Dr. H. L. Daiell, Director of Research, of Lakeside Laboratories, Milwaukee.

⁵ Radioactive mercury ($\text{Hg}^{203,201}$) was obtained from the Isotopes Division of the Oak Ridge National Laboratories.

MATERIALS AND METHODS

Fifteen subjects were studied. All except one were patients on the medical wards at the Charity Hospital. Certain clinical information concerning these subjects is presented in Table I.

The subjects were permitted to rest comfortably in bed in an air-conditioned room for 30 to 60 minutes in order to attain a stable state. Whenever the subject's clinical condition permitted, samples of urine were collected by means of a bladder catheter.

Two cc. of the radioactive mercurial diuretic, containing 78 mg. of total mercury, was injected intravenously over a period of about 20 seconds. Collection of blood samples was begun simultaneously with the beginning of the injection. Two types of collections were made: 1. In some subjects blood was withdrawn, by means of a syringe and a heparinized 20-gauge needle, from an antecubital vein contralateral to that into which the injection had been made. For the first two to three minutes, samples were collected as rapidly as 2 cc. of blood could be withdrawn (approximately four to eight seconds). The interval between collections was progressively increased every five to 10 minutes until at the end of one hour, collections were being made every 15 to 30 minutes for the remainder of the study, which lasted 100 to 180 minutes in all. 2. In another group of subjects, blood was taken from a femoral artery. It was allowed to flow freely from the open needle for the first two to three minutes, the time between collection of 2 cc. samples varying from two to five seconds. This interval was then progressively lengthened as described for the venous collections.

The blood samples were centrifuged and 0.3 cc. of the serum was dropped upon a filter paper disc, allowed to dry and cemented to a metal disc for counting.

Urine was collected as rapidly as samples of sufficient quantity for counting could be obtained. There was usually an interval of five to 15 seconds between collections. After the period of rapid collections of the blood samples, a sample of urine was obtained as nearly coincident as possible with the time of each blood sample.

Radioactive measurements were made with thin mica-window Geiger-Müller counter tubes or a continuous gas-flow counter tube. All measurements were recorded as counts per minute per cubic centimeter of fluid and were corrected to values corresponding to an injected dose of radiomercury with an activity of 10,000,000 counts per minute.

TABLE I
Summary of clinical data of the 15 patients studied

Subject	Age	Sex	Weight	Diagnosis	Status	Severity of edema	Previous mercurial diuretic
1	58	M.	—	Cirrhosis with ascites	Stationary	2+	None
2	40	F.	153	Hypertensive cardiovascular disease, congestive heart failure	Stationary	3+	Four days prior
3	64	M.	160	Hypertensive cardiovascular disease, congestive heart failure	Improving	3+	None
4	59	F.	139	Hypertensive and syphilitic cardiovascular disease; congestive heart failure	Worse on admission; improved after mercurial diuretic	4+	None day before
5	53	M.	140	Syphilitic heart disease, congestive heart failure	Improving	0-1+	None
6	58	M.	154.5	Arteriosclerotic heart disease, congestive heart failure	Rapidly improving	3+	None
7	34	M.	120	Congenital heart disease; unilateral lymphedema, right leg	No failure; stationary	4+ right leg	None
8	21	F.	92	Cervical lymphadenitis	Improving	0	None
9	33	M.	155	Pulmonary abscess	Recovered	0	None
10	60	F.	121.5	Diabetes	Controlled	0	None
11	34	M.	176	Chronic malaria	Recovered	0	None
12	21	F.	106.5	Postpneumonia	Recovered	0	None
13	61	M.	135.5	Lymphoma	Stationary	0	None
14	32	M.	126.5	Peptic ulcer	Recovered	0	None
15	34	M.	156.5	Amebic colitis	Improving	0	None

DATA AND METHODS OF ANALYSIS

Since the experimentally observed values of this study could not be made to fit precisely any regularly shaped curve, it may be considered better to abandon the idea of ever being able to define the regression of mercury from the blood until the methods of biologic analysis have been considerably improved. To take this course would undoubtedly remove criticism from the analyses and would eliminate the development of erroneous concepts. However, there would be little purpose in the mere presentation of observed values of blood concentration for radiomercury. Furthermore, if the nature and significance of the mathematical analyses of the data observed are properly understood, and if it is also recognized that such analyses extremely oversimplify the physicochemical processes related to the regression in concentration of mercury, so that they represent only an attempt to approach the definition of these complex processes, no misconceptions should result and discussions should follow. The latter point of view has been accepted for the presentation of these data, and discussions will include mathematical expressions which are only *approximations* of the biologic processes involved in the observed data.

The mathematical approach to the analysis of blood regression curves of radiosodium in dogs and in guinea pigs has been presented in detail by Gellhorn and associates (1), and in man by workers in this laboratory (2). Again, this method has been employed as an arbitrary approach to the analysis of the concentration-time course of radiomercury in man. The observed values were plotted on semilogarithmic paper and a close-fitting curve (frequently referred to below as the "mother" curve) was drawn in by inspection (Figure 1). The general equation for such a curve is:

tion for such a curve is:

$$C_p = A_1e^{-b_1t} + A_2e^{-b_2t} + A_3e^{-b_3t} + \cdots A_ne^{-b_nt}, \quad (1)$$

where C_p is the concentration of radiomercury in the serum at time (t).

$A_1, A_2, A_3, \cdots A_n$ = the respective amounts of the tracer which are regressing at the different rates.

$b_1, b_2, b_3, \cdots b_n$ = the rates of movement per minute of the respective amounts of the tracer out of the serum. The absolute values of these symbols indicate the portions of $A_1, A_2, \cdots A_n$, respectively, which leave the serum per unit of time.

There are numerous rates of movement or regression contributing to the observed curves, but because of the nature of the data and the curves, it was considered impractical to carry the analysis into more than three rates. During the interval of these studies the concentration of radiomercury in the serum continued to decline but never reached a constant value; therefore, the absolute value of b_3 in the third member of the equation was neither zero nor small enough to be considered as zero. This differs from the regression of sodium in that the concentration of the latter approached a constant value more closely. In fact, in the sodium studies such a value was considered for convenience to exist and, therefore, the C_{eq} value was employed, or b_3 was considered to equal zero (1).

The portion of the equation represented by the expression $A_2e^{-b_2t}$ was the tangent drawn through those points which most closely approached a horizontal and straight line in the "mother" curve (Figure 1). Selected values along this line extending to the ordinate ($t=0$) were subtracted from simultaneously occurring values along the "mother" curve. These differences were plotted, and a curve was drawn through the points. The expression of

the tangent to this new curve through the points which most closely approached a straight line was represented by $A_2e^{-b_2t}$. Selected values along this line extending to the ordinate were subtracted from simultaneously occurring values of the remainder of the curve not tangent to the line represented by $A_2e^{-b_2t}$; the differences were again plotted and a line was drawn through these points. The expression of this final "daughter" line, or regression rate, is represented by $A_1e^{-b_1t}$. It is evident from Figure 1 that it would have been impractical to carry the analysis further. Therefore, there appear to be at least three major rates of regression, each probably representing many physicochemical processes mathematically integrated to define the declination in concentration of mercury in the plasma of man. The sum of the values along these "daughter" curves at any time (t) represents the total concentration of the isotope in the plasma at that time, expressed graphically by Figure 1 or by equation (1). A discussion of the significance of these various regression rates will follow.

When the observed values from about two to about 200 minutes are plotted on logarithmic coordinates, they tend to lie along a straight line, the equation for which is $C_p = At^{-b}$, where

C_p = concentration of radioactive mercury in plasma at any time (t)

A = a constant which is numerically equal to the concentration of radioactive mercury in the plasma at one minute

t = time in minutes after injection

b = ratio of percentage change in concentration to percentage change in time (the slope of the curve on logarithmic coordinates).

Figure 2 permits the comparison of the curves of observed values for a subject plotted on rectilinear, semilogarithmic and logarithmic coordinates.

The regression curves of five of the 15 subjects studied were chosen for critical analysis. In these five the specific radioactivity of the plasma was sufficiently great to insure a high degree of accuracy in counting throughout the period of study. In Figure 3 these values are plotted on rectilinear (lower curves) and logarithmic coordinate (upper curves) systems. The regression curves or rates of regression of mercury from the plasma were similar for all 15 patients. Figure 4 illustrates a composite curve of all patients plotted on the semilogarithmic coordinate system. The degree of the

Three regression rates are shown and defined by the equation $C_p = 4350e^{-0.188t} + 1000e^{-0.169t} + 1115e^{-0.00169t}$.

FIG. 2. CONCENTRATION-TIME COURSE OF RADIOMERCURY IN THE PLASMA OF SUBJECT 5
PLOTTED ON THREE DIFFERENT COORDINATE SYSTEMS

Note that a considerable number of the observed points tend to lie along a straight line drawn on the logarithmic coordinate system.

individual variations precluded a differentiation of the curves or rates of regression of one clinical state from that of another, since small differences would have no statistical significance in such a limited series.

Figure 5 illustrates the regression curve obtained in similar experiments with the use of Na^{22} as a tracer.⁶ The regression curves of one of the studies with radioactive mercury and one with radiosodium plotted on logarithmic coordinate system permit comparison of the concentration-time course of these elements in the plasma of man. The differences are self-evident, especially those existing after approximately 200 minutes.

⁶ These studies were conducted primarily for other purposes at Grady Hospital, Emory University Medical School, Atlanta, in collaboration with Drs. A. J. Merrill and Heywood Turner. The samples were collected in Atlanta and brought to New Orleans for counting.

DISCUSSION

The interpretation of the regression curves obtained for any tracer is complicated by the combination effects of simultaneously occurring phenomena. This is particularly true in the initial portion of the curves, since all processes concerned, rapid and slow, are manifested at this time, when the greatest changes in concentration are also taking place. Progressively the tracer recording those factors responsible for rates of rapid change approaches equilibrium level and manifests itself less and less in the completed regression curve.

As has been demonstrated previously for sodium (2), and in these studies for mercury, there are essentially three separate major regression rates which contribute to the decline in concentration of the tracer in the serum. Obviously, the *initial* rate of regression of the concentration of radio-

FIG. 3. THE CONCENTRATION-TIME COURSE OF RADIOMERCURY IN THE PLASMA OF SUBJECTS 1-5 PLOTTED ON BOTH RECTILINEAR AND LOGARITHMIC COORDINATES

The coordinates for the logarithmic graph are on the top and the right of each graph and for the rectilinear on the left and bottom. The equations shown were obtained by the semilogarithmic graphic method of analysis described in the text.

FIG. 4. THE MEAN OBSERVED CURVE AND EQUATION OF CENCENTRATION-TIME COURSE OF RADIOMERCURY IN THE PLASMA OF 15 SUBJECTS

FIG. 5. THE PLASMA CONCENTRATION-TIME COURSE OF RADIOSODIUM COMPARED WITH THAT OF RADIOMERCURY IN TWO DIFFERENT SUBJECTS PLOTTED ON LOGARITHMIC COORDINATE SYSTEM

Note that whereas the curves are similar, they differ in the early portion, and that after 200 minutes the curves separate, the concentration of the mercury declining rapidly, with that of sodium being maintained. The ordinate values for both mercury and sodium were rendered comparable.

mercury in the plasma is influenced by the phenomenon of mechanical mixing. Figure 6 illustrates the ascension of concentration as well as the early portion of regression. A column of blood passing through the antecubital vein during the period of injection will contain a high concentration of radio-mercury. The local variations in concentration within the column will vary with the rate (force or linear rate and volume) of delivery of the radioactive substance. Since the collection of the blood samples begins simultaneously with the injection of the labeled substance, the first few samples collected will contain no radiomercury, the time of appearance of the tracer being dependent upon the circulation time and the rate and force of injection. When the tracer-containing blood column passes through the right side of the heart, its specific radioactivity is reduced by dilution with blood returning from other parts of the body; in the pulmonary vessels vigorous mixing takes place; and upon entering the left chambers of the heart, the radioactive column undergoes further mixing. Several ventricular contractions, at least as many as occurred during the time required for injection of the radio-mercury into the antecubital vein, are required to force the greater portion of the radioactive column of blood into the systemic circulation. From the moment the left ventricle receives radioactive blood, all blood leaving it will be radioactive because:

1. The column of blood into which the injection was made will contaminate the walls of all vessels through which it flows, which in turn contaminate in-flowing nonradioactive blood.

2. The blood which contains radioactive mercury ejected from the left ventricle will flow through vascular circuits of variable length, returning from the shortest (coronary circulation) before the return from the longest (lower extremity) has begun. This effects rapid, complete mechanical mixing and early, continuous return of radioactive blood to the left ventricle.

3. The linear velocity of blood flow through a vessel decreases from the center of the lumen of the vessel to the wall, the flow being almost zero at the surface of the wall. This phenomenon continuously increases the length of the column of radioactive blood, so that a continued flow of radioactive blood into the heart is maintained and mechanical mixing is encouraged. The process of

axial flow and surface skimming in vessels other than the segment receiving the injection will tend to delay mechanical mixing.

Under ideal experimental conditions the tracer substance should be completely mixed and distributed homogeneously in the blood at the instant of injection. A concentration-time curve would then be concerned with biologic phenomena other than mixing. Obviously, this ideal experimental condition cannot be achieved. An alternative approach might consist in delaying observations until mixing was completed; this, however, would be unsatisfactory because the movement of mercury into some compartments might be so rapid that the mercury in the blood might reach equilibrium with that in these compartments during the period allowed for mixing and before the observations are begun. The physiologic data available today strongly suggest that mixing has very little or no influence upon the regression curve after 30 minutes, probably negligible influence after 15 minutes in all subjects and even after one or two minutes in some subjects.

It becomes evident, therefore, that with rapid loss of a tracer substance from the blood and with relatively slow mechanical mixing, it is impossible to obtain an absolute picture of the true rate of loss of a tracer from the blood stream of man. It is also apparent that a true picture cannot be obtained from the later periods alone of the regression curve, because the tracer method is dependent upon the principle that all turnover phenomena, regardless of number and rate, are occurring at all times of study, special physiologic situations excluded.

It is safe to state that the initial portion of the concentration-time curve is the resultant of all the regression forces acting on mercury in the plasma stream of man and that the initial regression rate expressed as b_1 (Figures 1 and 4) is a manifestation largely of mixing processes occurring simultaneously with other rapid biologic phenomena of a physicochemical nature, such as fixation to protein molecules and cell surfaces. The other rates of regression are probably so little influenced by mixing that this phenomenon may be eliminated from serious consideration except insofar as mixing or continued circulation of the blood and other body fluids is necessary to insure satisfactory continuation of the other physicochemical processes

more directly responsible for the concentration-time course of mercury in the plasma.

The second regression rate is dependent upon those factors which are more apparent after the mixing process has been completed, for example, slower rates of diffusion into tissue spaces, cells, bone, and other sites of the body. Some of these have been discussed for sodium (3) and will not be repeated in detail.

It is well to realize that when Na^{24} or Na^{22} is employed as a tracer and is added to an organism such as man, it labels an already-existing, dynamic state of turnover of sodium among the various compartments within the body, *i.e.*, in the normal subject, except under special circumstances, the sodium space is already saturated with relatively large quantities of nontracer sodium. Therefore, the various components of the regression curves of tracer sodium represent its movement into sodium compartments already in a steady state concerned with active processes in dynamic equilibrium. Mercury, on the other hand, does not exist within the body under comparable conditions. That which is present normally in the body is apparently a contaminant and exists in relatively small quantities (4). It is possible, however, that

the "saturated" state for mercury in the body is zero concentration and that the body mechanisms are set to maintain this level. Nevertheless, there exists essentially a "turnover pattern" for mercury, which, unlike that for sodium, is not active. These innumerable turnover rates or regression processes for mercury manifest themselves only when the element is present, that which is normally present as a contaminant being disregarded. Thus, the radioactive mercury injected as an extremely small part of a total of 78 mg. of mercury in the mercurial diuretic labels practically all of the mercury which exists in the body (4) and which activates the "turnover patterns" for mercury. The regression curves of the radioactive mercury then must represent partially the migration of mercury into "depots" or "relatively fixed" compartments to fill "potential mercurial spaces." The result is an essentially unidirectional loss of mercury from the circulating serum rather than an exchange process already in equilibrium. The compartments into which mercury moves most probably include those systems concerned with the protection of the body from toxic effects of this foreign substance and with its subsequent excretion, for example, the liver, kidneys and cells and

FIG. 6

A. The ascension and regression of the concentration of radiomercury in the plasma for the first 20 minutes after injection.

B. The first four minutes of curve A more clearly illustrate the early variations in concentration. Note that radioactivity first appeared in the blood of the femoral artery between 35 and 40 seconds after the beginning of the injection into an antecubital vein. Twenty-two seconds were required for the injection.

The intersection (extrapolated) on the ordinate at 2,800 c.p.m. indicates the concentration if mixing were complete at t_0 . Except for errors due to the loss of mercury from the plasma during the first three minutes, the ratio of the injected dose to this extrapolated concentration "indicates" the mercurial space which at t_0 is also the plasma volume, since mercury does not adhere to erythrocytes in significant amounts.

FIG. 7

The interrupted line indicates theoretic concentration of radiomercury in the plasma calculated from that excreted in the urine and compared with the observed concentration of radiomercury in the plasma.

protein compartments not in the blood stream. It is likely that the recorded regression phenomena for mercury would be entirely different if the mercury depots were already saturated and the turnover processes were progressing at full pace instead of existing merely as "potential turnover patterns."

After the relatively rapid phenomena have manifested themselves in the first two regression rates, the relatively slow excretory rate is more clearly observed as a significant part of the third regression rate (Figures 1 and 7). That this third rate of decline in concentration of the radioactive mercury in the serum is a reflection primarily of urinary excretion is supported by the fact that the urinary excretion appears to account for a considerable part of the loss of radiomercury from the serum of some subjects beyond approximately 60 minutes after the time of injection. In other subjects the urinary excretion may not account for as much of the decline but is responsible for a substantial fraction of the regression from the blood. Details of urinary excretion will be presented elsewhere. Other routes of excretion undoubtedly influence this portion of the curve also.

Since the segment of the curve of the concentration-time course of radiomercury in the interval from about two to 200 minutes appears to be almost linear on logarithmic coordinates (Figures 2 and 3), the ratio of the percentage change in concentration to percentage change in time is nearly constant in this interval. The significance of this has not been fully developed.

It should be pointed out that the differences in the regression curves of sodium and mercury (Figure 5) are probably due to the differences in the respective phenomena which they represent. The rate of regression of sodium is more rapid early and considerably less rapid later. This is expected, since sodium diffuses more readily but is excreted more slowly than mercury.

The relationships of concentrations of radioactive mercury in blood serum to those in other biologic fluids, including urine, are under study at the present time and will be discussed elsewhere. With better understanding of the nature of the regression of mercury from the plasma, other biologic studies employing mercury in man can be better planned and evaluated. Without detailed knowledge of the concentration-time course of mercury in the blood plasma, accurate experiments concerned with blood values would be impossible.

SUMMARY

The concentration-time course of a mercurial diuretic labeled with radioactive mercury and injected intravenously has been studied in 15 human subjects. Analysis of the regression curves demonstrates that there are at least three major exponential rates responsible for the decline in concentration of mercury in the plasma. The first rate is apparently dependent to a large extent upon mechanical mixing; the second is possibly due to relatively rapid adsorptive, chemical and diffusion phenomena with migration into dynamic and more stable compartments; the third rate is

most probably a reflection mainly of excretory processes, principally urinary. It was not possible from these data to draw any conclusions as to differences because of the various clinical states in the subjects studied. Comparison of these curves with those similarly obtained for sodium indicate that there may be slight differences in the early portions of the regression curves and that great differences exist in those portions of the curves dependent upon the excretion of the isotope. The concentration of sodium in the plasma practically reaches an equilibrium, whereas the concentration of mercury may reach a steady state but does not approach an equilibrium due, in part, to rapid elimination.

These observations make possible a better understanding of the pharmacodynamics of mercurial diuretics and certain physiologic phenomena and

thus facilitate better planning of experimental studies concerned with mercurial diuretics *necessarily based upon plasma concentration of mercury*.

A STUDY OF CERTAIN ASPECTS OF BLOOD COAGULATION IN THE POSTOPERATIVE STATE IN CONGESTIVE HEART FAILURE AND IN THROMBOPHLEBITIS

By NOBLE O. FOWLER,¹ WITH THE TECHNICAL ASSISTANCE OF SHIRLEY ROEHM AND HAROLD PERLMAN

(From the Cardiac Laboratory, Cincinnati General Hospital, and the Department of Internal Medicine, University of Cincinnati)

(Received for publication January 18, 1949)

In recent years a number of tests have been designed for the purpose of detection of accelerated blood coagulation. Among these are the lusteroid tube coagulation test (1-4), the silicone tube coagulation test (5), the modified clot retraction test (6), the modified Lee-White clotting test, employing three test tubes instead of one (7), the heparin retarded coagulation test of Waugh and Ruddick (8, 9), the heparin tolerance test (10, 11), and the prothrombin time determination, using both whole and dilute plasma (12-14).

The study reported herewith was undertaken for the following purposes. First, it was desired to ascertain whether or not there is any correlation among the various tests themselves. Second, it was decided to determine whether any of these tests can be used to predict thrombophlebitis in patients. Finally, the incidence and duration of hypercoagulability in the postoperative state was studied, as well as the incidence of hypercoagulability in congestive heart failure. Incident to doing these studies, observations were made on the effect of variation of tube size and temperature upon the clotting time of blood in the Lee-White test. Further, in doing the heparin tolerance test, blood was withdrawn almost simultaneously from the vein into which the heparin was injected and from a vein of the opposite arm. Clotting times were run on each sample and the results were compared.

MATERIAL

For the study on postoperative patients, a group of 29 patients in the Cincinnati General Hospital who had had recent major surgical operations was selected at random. These 29 patients and three additional patients having acute thrombophlebitis were used to determine the correlation among the various tests. The problem of hypercoagulability in congestive heart failure was studied in 27

patients suffering from cardiac insufficiency on the medical wards of the Cincinnati General Hospital. A group of house officers, nurses, technicians, and ambulatory psychiatric patients were used as normal controls. Persons from both the control group and from the postoperative group were used to study the effect of variation in temperature and tube size upon the Lee-White clotting test. Persons from both groups were also used to study the effect of the veins chosen in performing the heparin tolerance test.

METHODS

The 29 postoperative patients and the three patients having acute thrombophlebitis were each studied by means of six tests which were run simultaneously. The same series of six tests was repeated on seven of the postoperative group later in their postoperative courses. The six tests employed were the modified Lee-White clotting test, the lusteroid tube coagulation test, the prothrombin time on whole and on 12.5% plasma, the Waugh-Ruddick heparin retarded coagulation test, and the heparin tolerance test. The 27 patients suffering from congestive heart failure were studied by means of the lusteroid tube coagulation test and the modified Lee-White test using three dry test tubes and an oiled syringe. Fifty of the control group were studied with the lusteroid tube coagulation test and the modified Lee-White test, using three test tubes and an oiled syringe. Twenty of the control group, all ambulatory psychiatric patients, were studied with the heparin tolerance test and the modified Lee-White test, using three saline-rinsed test tubes and a saline-rinsed syringe. The whole and dilute plasma prothrombin times were studied in 28 ambulatory psychiatric patients. The Waugh-Ruddick test was studied by means of 25 tests on a series of 15 persons in the control group.

PROCEDURE

1. Modified Lee-White test

This test was run essentially as described by Lee and White (15), with the exception that three test tubes were used instead of one. The second tube was not tilted until clotting had occurred in the first, and the third tube was not tilted until clotting had occurred in the second. The time required for clotting in the third tube was taken as the clotting time. This test was run in a constant tem-

¹ National Institute of Health Postdoctorate Research Fellow.

perature water bath at 37° C as suggested by Quick (16). This test was also run on each patient using three dry test tubes and an oiled syringe.

2. Prothrombin time on whole and 12.5% plasma

The method described by Quick (17) was employed, using Squibb thromboplastin.

3. Lusteroid tube coagulation test

The method used was similar to that of Kadish (1, 2), except that three tubes were used instead of one, the reading being taken from the third tube. The tests were run in a constant temperature water bath at 37° C. Blood was used only if obtained at the first attempt at venipuncture. Specimens were discarded if bubbling or frothing occurred in the syringe. The lusteroid tubes were 12.5 mm. in diameter. They were cleaned with sodium lauryl sulfonate, as recommended by Kadish (1, 2).

4. Waugh-Ruddick heparin retarded coagulation test

This test often shows acceleration of coagulation when the Lee-White test is normal. The method employed was that described by the original authors (8, 9), except that all tests were run in a water bath at 22.5° C, as recommended by Whittaker (18). This author found that a rise in temperature caused much more rapid clotting in the Waugh-Ruddick test; we have had a similar experience. Whittaker selected 22.5° as the average winter room temperature. Waugh and Ruddick did their tests at room temperature (8, 9). He found clotting times in normals comparable to those of Waugh and Ruddick when the tubes containing the blood were placed in a water bath at a temperature of 22.5° C (18). The criterion of increased coagulability in this test was that suggested by Ogura (19), namely, a coagulation time of 60 minutes or less in each of the last three test tubes employed.

5. Heparin tolerance test

Hagedorn and Barker's (11) modification of the test of deTakats (10) was employed. However, in consideration of the marked effect of temperature variation upon the clotting time of blood (16, 18), the tests were done in a constant temperature water bath at 37° C. Three test tubes, each 8 mm. by 75 mm., were employed.

As suggested by Hagedorn and Barker (11), one sample of blood was drawn 10 minutes after the injection of 25 mg. of heparin in 2.5 cc. of solution intravenously. The heparin was injected at a constant rate, requiring 30 seconds for its administration.

RESULTS

The findings in the control group will be given first. These are shown in Table I. In 50 controls, the range for the modified Lee-White test, using an oiled syringe, was from 9 to 23.5 minutes; the range for clotting in lusteroid was from 19 to 40 minutes in this group. In 20 controls, the range for the modified Lee-White test, using saline-rinsed glassware, was from 9 to 21 minutes. The mean for the 20 determinations was 11.58 minutes when saline-rinsed tubes and syringes were employed; the mean for 50 similar tests using an oiled syringe and dry test tubes was 14.77 minutes. The standard deviation for the 50 determinations using oiled syringes was 3.34 minutes. The standard deviation for the 20 determinations using a saline-rinsed syringe was 4.36 minutes. The standard error of the difference between the two means of 14.77 minutes and 11.58 minutes was found to be 1.08 minutes. The observed difference was 3.19 minutes. Since the observed difference in the means was three times the standard error of the difference, this was felt to be a significant finding. This difference would occur by chance only once in 370 tests. Ten minutes after the injection of 25 mg. of heparin intravenously, the modified Lee-White clotting time was increased from two to slightly more than four times that before heparin.

Among 28 control ambulatory psychiatric patients, the range for the prothrombin time run on whole plasma was from 11.5 to 16.00 seconds. The range for the prothrombin time on 12.5% plasma was 26 to 37 seconds; the range for the difference

between the whole and dilute plasma prothrombin times was from 14 to 22 seconds.

Acceleration was considered present in any test when the result obtained was lower (*i.e.*, less time) than was found in any control test of the same method. Of the 29 postoperative patients, acceleration was found as follows: by Waugh-Ruddick, 19 showed acceleration; by lusteroid, 10; by heparin tolerance, six; by whole plasma prothrombin time, five; by 12.5% plasma prothrombin time, three; by modified Lee-White test run in saline-rinsed glass, three. The results are summarized in Table II. As seen in Table II, the correlation among the various tests was poor. Of 10 patients showing abnormal tests in lusteroid, seven showed abnormal Waugh-Ruddick tests. However, of six patients with abnormal heparin tolerance, only two had accelerated Waugh-Ruddick tests, and only two had accelerated clotting in lusteroid. Of five patients having abnormally short whole plasma prothrombin times, four showed abnormal Waugh-Ruddick tests, but only two had

accelerated clotting in lusteroid. The only patient among the 29 tested who developed venous thrombosis had normal values for all tests. This patient was a 42 year old colored man, who had had a hernia repaired eight days prior to the thrombosis. The clotting tests were performed five days prior to the occurrence of the thrombosis.

In order to ascertain how long the state of accelerated coagulation may persist after operation, the same series of six tests was repeated on seven of the 29 patients later in their postoperative courses. The results are shown in Table III. As may be seen in the table, evidence of hypercoagulability was found as late as 12 days after operation in some instances.

Our clotting times after 25 mg. of heparin were shorter than those obtained by Hagedorn and Barker (11), probably because our tests were performed at 37° C, whereas their tests were performed at room temperature, which is generally much lower. In order to study the effect of temperature upon the results obtained in this test, we

ran clotting times on samples of blood drawn 10 minutes after giving 25 mg. of heparin intravenously to each of 10 patients. One part of the sample was tested at 22.5°, the average winter room temperature, and the other portion was done at 37°. As may be seen in Table IV, the clotting time was appreciably longer at 22.5° in all instances save two. The average clotting time at 22.5° was 26.5 minutes, and at 37°, 13.4 minutes.

In order to study the effect of test tube size upon the results obtained in doing the Lee-White clotting time, this test was done in glass tubes of

two different sizes, one 8 mm. by 75 mm. and the other, 13 mm. by 100 mm., using identical samples of blood. As shown in Table V, this procedure was performed in 14 instances. It may be seen that the clotting times were longer in the small tubes in nine instances; the clotting times were equal in one case; in the four remaining instances the clotting times were longer in the large tubes. Both Kadish (1) and Quick (16) found clotting times to be longer in large than in small glass tubes.

Whether or not the veins selected in performing the heparin tolerance test affected the result was also studied. In 14 instances, the one tube Lee-

White test was performed 10 minutes after injecting 25 mg. of heparin intravenously. Blood was drawn almost simultaneously from the vein into which the heparin was given, and from the vein of the opposite arm. As seen in Table VI, the results were the same or nearly so in seven instances. In six cases, the clotting times were considerably longer on blood drawn from the vein which had received the heparin. In one instance, the blood drawn from the vein receiving the heparin did not clot after 12 hours. In one case, the clotting time was significantly shorter on blood taken from the vein receiving the heparin. This finding would seem to imply that in some instances there is retained in the vein injected with a foreign substance a larger proportion of substance than is found in the general circulation.

Note: Each patient received 25 mg. heparin intravenously. After 10 minutes, one tube Lee-White clotting times were run on blood drawn almost simultaneously from the vein receiving the heparin and from the vein of the opposite arm.

DISCUSSION

The clotting mechanism in postoperative patients was studied by Potts and Pearl (20), Dawbarn, Earlham, and Evans (21), and by Shapiro Sherwin, and Gordimer (22). These investigators found that the platelet count tended to fall during the first three days postoperatively, but that it began to rise on the sixth postoperative day, and reached a peak on the tenth to 14th postoperative

day. They found little change in the clotting time as determined by the usual methods.

The abnormalities in the clotting mechanism found by us do not parallel the changes in the platelet count found by the above investigators; in general we found abnormalities in clotting earlier in the postoperative course in this study. Not only were the manifestations of derangements in the clotting mechanism found earlier here, but the change seemed to be greater earlier in the postoperative course than in the 10 to 14 day postoperative period when the maximum changes in the platelet count were found. However, as seen in Table III some cases still showed acceleration of clotting as long as 12 days after operation.

The finding of accelerated coagulation as judged by the Waugh-Ruddick test in 19 of the 29 postoperative patients is in keeping with the findings of Waugh and Ruddick (9), whose study of postoperative patients revealed accelerated coagulation 24 hours after operation; this acceleration was present seven days following operation. Our finding of acceleration of coagulation in two-thirds of 29 postoperative patients, a finding which persisted at least 12 days after operation in some cases, may be considered in regards to possible routine postoperative anticoagulant therapy.

The Waugh-Ruddick test seemed most sensitive of the tests employed in detecting the effect of operative trauma. In this connection, it is of interest to note that Flinn (23), following the administration of digitalis in man, found acceleration of coagulation as shown by the Waugh-Ruddick test, whereas the Lee-White test and the prothrombin time on whole and dilute plasma showed no change. The extreme sensitivity of the Waugh-Ruddick test is shown by its acceleration in response to such procedures as operative trauma and digitalization; this would seem to detract from its value in the prediction or diagnosis of venous thrombosis. The non-specificity of this test is further illustrated by the fact that Waugh and Ruddick found that bed rest alone caused acceleration of coagulation (9).

It is of interest to note the lack of correlation between the Waugh-Ruddick test and the heparin tolerance test, since heparin is used to prolong the coagulation of blood in both instances, in the former *in vitro* and in the latter *in vivo*. In partial explanation of this finding, the statements of

Best and Jaques (24) may be cited. These writers state that if there is mixture of the same amounts of heparin and blood *in vivo* and *in vitro*, the clotting time will be longer *in vivo* if moderate amounts of heparin are used. Best and Jaques also state that the renal threshold for heparin is quite low, and that there is rapid excretion of heparin into the urine if large doses are given intravenously. Further, even if heparin is not excreted into the urine, it disappears rapidly from the blood. Thus, variation in the rate of heparin destruction and heparin excretion have to be reckoned with in performing the heparin tolerance test. Since these factors are not operative in the Waugh and Ruddick test, the failure of the two tests to correlate may be explained.

The lack of correlation among all the tests might be explained in part by the onset of anxiety during the period of the test. DeTakats (25) has mentioned adrenal stimulation, such as by anxiety or fear, as a cause of increased coagulability of the blood. In a few cases we have found marked acceleration of coagulation in lusteroid tubes and marked increase of heparin tolerance when the patients were on the verge of an anxiety attack or delirium tremens. Other factors, such as type of anesthesia, the presence of an occult infection, or the administration of barbiturates might explain the variations in clotting from patient to patient in the postoperative group. However, since all six tests were done within a space of two hours on each postoperative patient, these last factors could not very well explain the lack of correlation in the individual patient; *i.e.*, these factors do not explain why some tests were normal and others abnormal in the identical patient at virtually the same time.

The prothrombin time of dilute plasma was less often abnormal than that of whole plasma. This was especially notable in the three thrombophlebitic patients, where the dilute plasma prothrombin time was normal in every instance, yet the whole plasma prothrombin time was shortened in all three. This finding is similar to that of Mahoney and Sandrock (26), who found a greater increase in prothrombin activity in their postoperative thrombophlebitis patients as shown by the test on whole plasma as compared to dilute plasma. Hurn, Barker, and Mann (27) also found that the prothrombin time of dilute plasma gave no more information as to hypercoagulability than the test as run on whole plasma. Tuft

and Rosenfield (28) concluded that accelerated dilute plasma prothrombin determinations could not be used for prediction or diagnosis of thromboembolic disease. In contrast, Shapiro (13, 14, 22) and Brambel and Loker (12) found the dilute plasma prothrombin time more sensitive to the state of hypercoagulability than the whole plasma prothrombin time.

Mahoney and Sandrock (26) found in their 58 normal postoperative patients a prolongation of the prothrombin time during the first three days following surgery. They found acceleration during this period only in those patients who subsequently developed thrombophlebitis. In our group, of 13 patients studied during the first three days postoperatively, none showed the prolongation of the whole plasma prothrombin time described by Mahoney and Sandrock (26). Further, the mean whole plasma prothrombin time in these 13 postoperative patients was 12.8 seconds, as compared with a mean of 13.5 seconds for the 28 controls. Among the 28 controls, the standard deviation for the whole plasma prothrombin time was 0.85 seconds. Among the 13 postoperative patients, the standard deviation for the whole plasma prothrombin time was 1.45 seconds. The standard error of the difference of the two means of 12.8 and 13.5 seconds was found to be 0.471 seconds. The observed difference was 0.70 seconds. This is not a significant difference.

Only one patient of this group of 29 postoperative patients developed thrombophlebitis after operation. The demonstration of frequent abnormalities in the six tests in so many of the 28 patients who did not subsequently develop thrombophlebitis would seem to indicate that none of these tests could be used to predict which patient is going to develop venous thrombosis following an operation. This statement is given weight by the fact that the only patient who did develop clinical thrombophlebitis showed no abnormality in any of the six tests which had been run five days previously.

It is thought worthy of comment that only one of the 27 patients having congestive heart failure showed an acceleration of coagulation in lusteroid tubes, and only two as measured by the three tube Lee-White test. This finding may be compared with that of Cotlove and Vorzimer (29) who found no shortening of the whole or dilute plasma pro-

thrombin time in 20 patients with congestive heart failure. It is also of interest to note that 25 of our 27 patients were receiving digitalis therapy in maintenance doses, yet little evidence of acceleration of clotting was found. Digitalis has been frequently mentioned as an accelerator of clotting (7, 25, 30). Ogura, Fetter, Blankenhorn, and Glueck (19) found some evidence of acceleration of coagulation in their patients as they were being digitalized, but found that this acceleration later disappeared in the majority, even though maintenance digitalis therapy was continued. Cotlove and Vorzimer (29) found that the administration of digitalis did not shorten the prothrombin time as determined on whole plasma or dilute plasma. Moses (31) found no change in heparin tolerance after the exhibition of digitalis. Flinn (23) found the Waugh-Ruddick test to show acceleration of coagulation after the administration of digitalis, but no acceleration was shown by the Lee-White test or by the prothrombin time on whole or dilute plasma.

SUMMARY

Twenty-nine postoperative patients were studied for evidence of accelerated coagulation. Nineteen showed acceleration by the Waugh-Ruddick test; ten showed acceleration in lusteroid tubes; six showed increased heparin tolerance; five showed shortening of the whole plasma prothrombin time; three showed shortening of the 12.5% plasma prothrombin time; three showed an acceleration by the modified Lee-White test.

The same tests were repeated on seven of these patients later in their postoperative courses and some showed persistence of hypercoagulability on the 12th postoperative day. The different tests did not correlate. The only patient who developed subsequent thrombophlebitis was normal to all tests. Three other patients with thrombophlebitis showed acceleration of coagulation in lusteroid tubes and shortening of the whole plasma prothrombin time. They were normal with regard to dilute plasma prothrombin time and the Waugh-Ruddick test. Of 27 patients with congestive heart failure, 25 of whom were receiving digitalis, only one showed acceleration of coagulation in lusteroid tubes, and two showed acceleration in the Lee-White test. Fourteen patients were given 25 mg.

of heparin intravenously. Ten minutes later, blood samples were drawn almost simultaneously from the arm vein into which the heparin had been injected, and from a vein in the opposite arm. In six of these 14 patients, the clotting time was significantly longer in the blood sample taken from the vein receiving the heparin when compared to the blood obtained from the opposite arm.

CONCLUSIONS

1. Hypercoagulability of the blood is a frequent finding in the postoperative state, and may persist as long as 12 days after operation.

2. The correlation among the Waugh-Ruddick test, prothrombin time on whole plasma, prothrombin time on 12.5% plasma, lusteroid tube clotting time, and heparin tolerance test is poor, suggesting that they are concerned with different factors involved in the clotting process.

3. We could not predict which postoperative patients were going to develop venous thrombosis.

4. When performing the heparin tolerance test and similar tests in which a substance is injected intravenously, and a sample of blood is later drawn for analysis, it is advisable to draw the blood from the vein of the opposite arm. The vein into which the substance is injected probably retains a larger proportion of that substance than is found in the general circulation.

5. Of the tests studied, the Waugh-Ruddick heparin retarded coagulation test appears the most sensitive. Its lack of specificity, however, would seem to indicate that it is of no value in predicting or diagnosing thrombophlebitis.

ACKNOWLEDGMENT

The writer wishes to acknowledge the very kind assistance of Dr. Helen Glueck.

STUDIES OF LUNG VOLUMES AND INTRAPULMONARY MIXING: NOTES ON OPEN-CIRCUIT METHODS, INCLUDING USE OF A NEW PIVOTED TYPE GASOMETER FOR LUNG CLEARANCE STUDIES

By J. B. BATEMAN,¹ WALTER M. BOOTHBY, AND H. FREDERIC HELMHOLZ, JR.

*(From the Mayo Aero Medical Unit and the Division of Physics and Biophysical Research,
Mayo Foundation, Rochester, Minn.)*

(Received for publication October 18, 1948)

INTRODUCTION

The measurement of lung volume by an open-circuit method (1, 2) is usually based on the redistribution of nitrogen contained in the lungs in such a manner that most of this gas is expelled and measured. Physically, this principle requires only the collection of the exhaled nitrogen in some diluent such as oxygen and the measurement of total volume and nitrogen concentration; the quantity of nitrogen involved can then be computed. In the usual procedure the subject breathes oxygen for a set period, the total expired air being collected in a gasometer; then the connecting tubes are washed with more oxygen and the final volume and nitrogen concentration in the gasometer are measured.

Such a method could be extended to the study of the nitrogen clearance process. The physical conditions which must be satisfied, however, are much more exacting than those which apply to measurement of lung volume. It becomes necessary to determine accurately (1) respiratory volume at various instants during the clearance process and (2) the total amounts of nitrogen in the external system at these instants. These requirements demand modification of existing open-circuit methods in the following particulars: *A.* It is necessary to avoid continuous flow of oxygen by-passing the experimental subject. Only by using a true demand system of oxygen supply can it be assured that all the gas collected has been involved in the tidal movement. *B.* It is necessary either to measure separate points on the clearance curve by doing several experiments, or to arrange for serial sampling of the expired gas, with simultaneous measurement of volume. The

latter expedient, which is preferable, implies in turn (1) the presence in the gasometer of some device to ensure rapid mixing of the gases introduced and (2) the elimination, as far as may be feasible, of tubes connecting the subject with the gasometer. If the latter condition is not satisfied, part of the gas exhaled in any breath will not reach the gasometer until the succeeding breath.

During experimental work described elsewhere (3, 4) some 30 modifications of the open-circuit method have been used in the measurement of lung clearance curves. It will perhaps be of value, in view of this extensive experience, to indicate the ways of meeting the foregoing technical requirements which have proved most reliable. This paper deals solely with the physical problems of measuring the volume and composition of expired gas and neither with physiologic sources of error nor with the interpretation of the data. Two distinct procedures, the "end-point sampling" method and the "serial sampling" method, will be described. The latter is greatly to be preferred, but it involves the use of special equipment.

THE END-POINT SAMPLING METHOD

Experimental arrangement. Figure 1 represents the arrangement which has been found most satisfactory. Oxygen is supplied from high pressure tanks after reduction to 100 pounds per square inch. This serves as the input line for a Pioneer dilutor-demand oxygen regulator, type AN6004-1, which has been modified by removing the dilutor cap and handle and the aneroid unit and sealing the opening with a gasket and bakelite plate. Thus the valve supplies only pure tank oxygen.² Since the operating suction is appreci-

¹ Present address: Physical and Chemical Division, Research and Development Dept., Camp Detrick, Frederick, Maryland.

² We are indebted to the National Bureau of Standards and to Lieutenant Commander Allison of the Naval Bureau of Aeronautics for this regulator.

able the regulator is loaded with a 15-gm. weight placed on the large diaphragm indicated in the lower portion of Figure 1.² The output side of the demand regulator is connected by large corrugated rubber tubing to a Krogh valve, to a three-way hand-operated valve of large bore and finally to the face mask worn by the subject. At a point slightly distal to the three-way valve, the inspiratory line communicates with the tube through which the expired gases pass, by way of a second Krogh valve, to the gasometer bell. The gasometer is of the Tissot type, of 100-liter capacity, modified by sealing the inlet tubes at their point of entry into the main chamber. This appreciably reduces the dead space. Welded to the roof of

the gasometer bell is a second manual three-way valve of large bore with a side-arm connected to a 5-liter rubber bag and vacuum line. The bag is used at the end of each experiment for mixing the collected expired gas in the gasometer, by being successively filled and emptied. The wire carrying the counterweight of the gasometer is supplied with a pen which indicates volume on a moving drum, not shown in Figure 1, during the collection of expired gas. The by-pass from the high-pressure oxygen supply to the gasometer indicated in the diagram serves for initial washing of the apparatus.

Attention may be drawn to (1) provision of a sampling tube for checking the composition of inspired gas, and (2) the valve assembly, consisting of two Krogh valves welded into a compact unit.

Analytic method. A modified Haldane method of gas analysis was used, the nitrogen residue being measured as the volume increment brought

² Evidence has been obtained that a certain amount of by-passing occurred in some of the experiments reported in the following papers as a result of failure of the valve to close completely when operated by persons with certain types of respiratory pattern. This source of error has now been obviated.

about after mixing with a larger measured volume of stored nitrogen. Duplicate analyses are usually reproducible to within 0.001 (0.10 per cent nitrogen).

The accuracy with which a given amount of nitrogen can be estimated after dilution with oxygen was investigated by progressively diluting a known amount of air (measured by displacement of water) in a gasometer of known dead space with measured amounts of oxygen and comparing the measured decreases of nitrogen concentration with those calculated from the volumes mixed (Table I). It seems fair to conclude from the final column of Table I that at no point in a clearance curve is the error in the total amount of nitrogen measured likely to exceed 100 ml. from this particular source of error; usually it will be much less. The accuracy seems to be

greatest when the nitrogen fraction in the gasometer is 1 to 3 per cent.

Accuracy of volume measurements. In the 100-liter Tissot gasometer, a movement of 1 cm. indicates a change of volume of about 2 liters. The scale can be read to about 0.25 mm., or 50 ml. This is adequate for most purposes provided it can be proved possible to determine the conditions of temperature and humidity to which the measured value applies. It has been found in repeated tests that the volume of expired air received by the gasometer does not undergo any observable change over a period of several minutes. Presumably, the gas leaving the subject at 37° C and saturated with water vapor is almost immediately cooled to the temperature of the gasometer and the corresponding pressure of saturated aqueous vapor is established. It follows

* Procedure: The gasometer dead space is originally filled with tank oxygen. A known volume of air is admitted to the gasometer by displacement with a weighed amount of water in an Erlenmeyer flask (column 1). A known volume of oxygen is then added, the gasometer volume is read (column 4) and a sample is removed for analysis (column 5). Then further oxygen is added and the procedure is repeated, the original volume of air in the gasometer being corrected at each stage for the amount removed in the sample (column 2). The corrected volume of air (column 3) can be compared with that calculated from the nitrogen analyses (column 6).

$$V_{\text{air}} = \frac{(V + D)(fN''' - fN)}{0.791 - fN}$$

where D = dead space of gasometer = 2,390 cm.³,
V = volume of gas in gasometer,
V_{air} = corrected volume of air in gasometer,
fN = nitrogen fraction in tank oxygen (usually about 0.003),
fN''' = nitrogen fraction in gasometer.

also that no measurable errors are introduced by transfer of gas to or from the water in the gasometer.

Gasometer dead space. Even when measures were taken to reduce the dead space of the Tissot gasometer, the value remained in excess of 2 liters. This is undesirably large and its presence has reduced the accuracy of our measurements in the early part of the lung clearance curve. A more serious drawback is the fact that this dead space is less constant than might be desired, since the position of the gasometer bell when the gasometer is "empty" is variable. This is difficult to eradicate in a gasometer of the Tissot type.

Procedure in end-point sampling method. For some hours before the experiment is started, the entire system is washed with a slow stream of cylinder oxygen. Analyses of the gas in various parts of the system are made. The gasometer is then emptied, the rubber bag is evacuated, and the three-way valve to the gasometer is oriented as shown in Figure 1. The subject is connected to the apparatus with a suitable face mask, with the three-way valve so turned that he is able to breathe room air. After doing this for a short time, he rapidly turns the three-way valve at the end of a normal expiration so as to be brought into connection with the oxygen supply system and the gasometer. He breathes oxygen for the desired number of breaths—ten for example—and at the end of the tenth exhalation, turns his three-way valve back to the original position. A volume reading is taken on the gasometer and the connecting tubes in the expiratory line are flushed with 10 liters of oxygen. The three-way valve on the gasometer is turned so that the rubber bag fills itself from the gasometer contents; it is then emptied by hand and filled again, and the cycle is repeated ten times. The gas is then deemed adequately mixed and samples are collected over mercury in a 100-ml. tube. In order to get further points on the clearance curve, the system is again washed with oxygen and after a suitable intervening period of at least 30 minutes, during which the subject breathes air, the entire procedure is repeated.

THE SERIAL SAMPLING OF COLLECTED EXPIRED AIR

The study of lung clearance curves by the method described in the preceding section is at

best a laborious procedure. In any extended investigation, it is desirable to develop methods for detailed recording of a single clearance process. Such a method, which would involve taking a series of instantaneous samples of mixed expired gas, would have further advantages, including the reduction of errors resulting from variations in the initial lung volume. For this and other reasons, methods for serial sampling have been devised.

Four new requirements must receive attention in connection with serial sampling: 1. Provision for rapid mixing of gases must be made, so that any sample is truly representative of the entire contents of the gasometer. 2. The volume of the tubes connecting the subject with the gasometer must be reduced because it represents a volume of expired air which, at every exhalation, fails to enter the gasometer and is thus unable to contribute to the composition of the mixed expired gas. 3. An improved sampling procedure is required, since it is necessary to take samples rapidly and at frequent intervals. 4. The gasometer dead space should be reduced.

A NEW GASOMETER ASSEMBLY FOR LUNG CLEARANCE STUDIES BY SERIAL SAMPLING

The gasometer. A new gasometer with associated equipment has been designed with the foregoing considerations in mind, together with the following additional points which appeared important: (a) low inertia of moving parts, (b) convenient and accurate recording of collected gas volume and (c) capacity large enough to hold most of the air expired during lung clearance but small enough for adequate accuracy in the recording of volume and also small enough to make it convenient to conduct a clearance measurement in two parts, since the final portion of the clearance curve can be more accurately determined in this manner than would be possible in a single protracted period of collection.

The plans for the new gasometer were placed in the hands of the Waters Conley Company, Rochester, Minnesota, which was responsible for mechanical details and for the construction of the apparatus.

A gasometer of the pivoted type (5, 6) appeared to offer decisive advantages, the form being such as to permit close approach of the subject, so that the dead space of the connecting tube can

FIG. 2. PIVOTED TYPE GASOMETER

Side view and sections showing positions of gas agitator, inlet tubes and sampling device. See text.

be reduced to a few cubic centimeters. Such an apparatus also appeared amenable to fine mechanical construction, so that the internal dead space could be much reduced. Moreover, since the bell is not freely suspended but can be accurately and rigidly pivoted, this dead space should be highly reproducible. Added to these advantages is the ease with which the necessary mechanical linkages can be made for recording gas volume.

The layout of the apparatus can be gathered from Figures 2 and 3. The gasometer bell consists of a wedge-shaped shell of about 60 liters capacity (Figure 2, D) made of sheet aluminum (roof 3 mm. thick; side walls 0.75 mm.) pivoted at one end (Figures 2 and 3, E) with "New Departure" precision ball bearings. It articulates in a water-filled well of the form indicated by C (Figure 2), which thus takes the form of a rectangular moat bounding a rectangular floor of sheet brass (Figure 2 [ii]). When the bell and the trough articulate, the volume of gas between them is completely enclosed by a water seal. The floor is pierced by several holes. These are conveniently placed near the axle of the machine. The centrally situated tube, J (Figure 2), of internal diameter 1.3 cm., serves for the introduction of expired gas. A narrow sampling tube, G, of internal diameter 0.3 cm., passes to the lucite distributor (see also page 684). Two wide apertures, F, are included, so as to make the apparatus rapidly and conveniently adaptable for use in open-circuit or closed-circuit measurements of

metabolic rate. Normally, these tubes are kept closed by brass plugs which pass in as far as the level of the floor of the gasometer chamber, thus eliminating additional dead space. Finally, an opening, H (Figure 2), in the center of the floor carries the driving shaft of a circulating fan set in a depression 10 cm. in diameter and 0.6 cm. deep. This fan, of centrifugal type, and its water-sealed bearing are shown in more detail in Figure 2 (iv).

The two recording systems are shown in Figure 3. For photographic recording, the horizontal axis about which the gasometer bell moves is linked by means of a flexible cable to a vertical axle, U, supported by two precision ball bearings and provided with a mirror (Figure 3 [iii]). For mechanical recording, a wire attached to the lowest peripheral point, M, of the gasometer bell passes over a fixed pulley, N, to the ink-writer pulley, P, and thence to a counterweight, O, which is adjusted to keep the gasometer bell very nearly balanced in all positions. The method of attachment of the recording wire to the gasometer bell is of some importance, since the effective point of attachment is determined by the tangent from the pulley, N, to the circular arc defined by the end of the gasometer bell. The point of attachment is therefore effectively constant for all positions of the bell, so that a linear relation between volume and recorded deflection is assured. A system of gears introduces the possibility of amplifying the volume record in accordance with the following figures: for direct recording, 1 liter volume change produces 6.5 mm. deflection; for amplified

FIG. 3. DETAILS OF RECORDING MECHANISMS OF PIVOTED TYPE GASOMETER
(SEE TEXT.)

FIG. 4. EXPERIMENTAL ARRANGEMENT USED FOR COLLECTING SERIAL SAMPLES OF EXPIRED AIR IN EVACUATED SAMPLE TUBES

Operation described in text.

recording, the deflection is 25 mm. Furthermore, a clutch system operated by the pulley, V, drawn in detail in Figure 3 (ii), enables the lower pen to operate as an indicator of total ventilation. This is not used in lung clearance measurements, but is useful in closed-circuit metabolism studies.

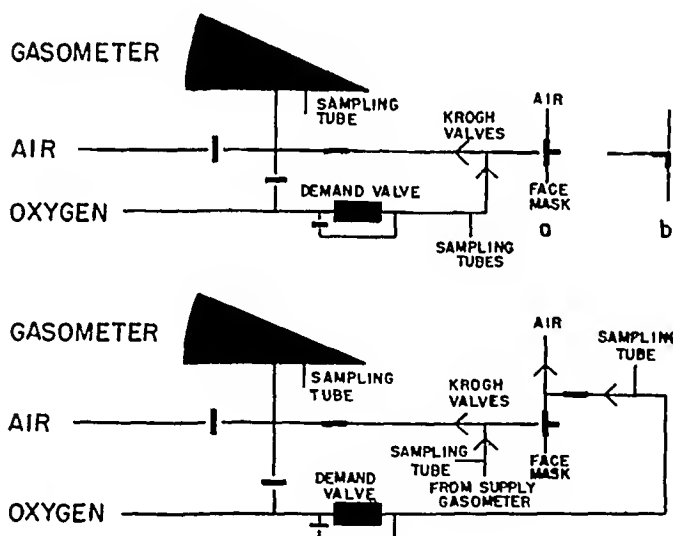

The entire apparatus is mounted with adjustable clamps on two steel pillars 7 cm. in diameter attached to a wheel base, vertical adjustment being facilitated by counterweights.

Sampling procedure. Samples from the gasometer are collected over mercury in evacuated 100-ml. Pyrex tubes. Twelve such tubes are connected through a lucite distributor to the sample tube of the gasometer (Figure 4). The tubes are evacuated by a Cenco pump before the experiment is commenced and the rest of the system, consisting of the dead space of the distributor, the 2-liter reservoir, and various mercury traps and connecting tubes, is kept evacuated throughout the experiment. When a sample is to be taken, the entire distributor is filled with gas from the gasometer; then the appropriate sample tube is opened and closed. Immediately thereafter, the distribu-

tor is once more connected to the vacuum line and is evacuated in time for the next sample. At the end of the experiment, mercury is admitted to the sample tubes so as to bring the samples to atmospheric pressure and reduce the danger of inboard leaks.

The mercury reservoirs shown in Figure 4 were necessary in order to free the mercury from air and to obviate the danger of contamination by inward leakage of air through flexible connecting tubes. It was found that both rubber and plastic tubing are permeable to air, so that without special precautions, large analytic errors were caused by air leaking into the mercury and thus being transferred to the gas samples. The mercury reservoirs were designed in such a way that during the preliminary removal of air from the system all flexible connecting tubes could be emptied and evacuated. The mercury itself could be agitated by inverting

1. NITROGEN ELIMINATION

2. NITROGEN RETENTION

FIG. 5. SERIAL SAMPLING ARRANGEMENT USED IN STUDY OF ELIMINATION AND RETENTION OF NITROGEN BY THE LUNG

(1) By collecting expired gas during the breathing of pure oxygen, (2) By collecting expired gas during breathing of air following prolonged inhalation of oxygen. Connecting tubes are represented by thin continuous lines. Thick lines indicate the presence of hand-operated valves. Arrows represent Krogh valves. The gasometer is a pivoted type apparatus of 60-liter capacity provided with a fan to accelerate mixing of gas collected. Serial samples of total expired gas are taken through the sampling tube in the floor of the gasometer, using the distributor shown in Figure 4.

the reservoirs by rotation about a central axle as indicated by the arrows in Figure 4. As soon as the reservoirs were restored to their original position and mercury was again introduced into the flexible tubing, it was possible to admit air to the reservoirs and to maintain the mercury at or above atmospheric pressure. The entire system, including the lucite distributor, was tested routinely for leakage by reducing the pressure to about 0.1 mm. of mercury and observing its constancy with a McLeod gauge (Stokes, type 276 AA).

Dead space. The volume of gas in the gasometer and fixed connecting tubes when the moving shell is completely collapsed was measured both by filling this volume with tank oxygen and diluting with a known amount of air or nitrogen, and also by filling with air and diluting with tank oxygen. Concordant and reproducible values were obtained. The volumes of the conducting passages distal to the Krogh valve assembly and of the connections from the Krogh valve assembly to the face mask (Figure 5) were determined from their physical dimensions. The dead space of the face mask was estimated in several persons by filling it with water and measuring the amount of water remaining after the mask had been placed over the face. As it was not feasible to perform this type of measurement on every subject, a single average value was used throughout. The three dead-space volumes, measured in milliliters, were (1) "internal" dead space of gasometer, d , 544 ml., with which may be contrasted the value of about 2,000 ml. in the modified Tissot gasometer used in the "end-point sampling" experiments; (2) "external" gasometer dead space, D , 85 ml.; (3) external "respiratory" dead space, d_c , 150 ml. (volume of mask and connecting tubes as far as Krogh valve assembly).

Mixing of expired gas in gasometer. During the experiments reported elsewhere (3, 4) the fan used for mixing the expired gases was operated by a small motor rated at 3,600 r.p.m. This fan was later found to be erratic in performance and mixing was not sufficiently rapid. The motor was replaced by one rated at 7,000 r.p.m. connected through a Variac transformer, and the rate of mixing was measured as a function of the transformer setting. The sampling error attained an acceptably low value with an undetermined motor speed somewhat less than 7,000 r.p.m. The magnitude of

these sampling errors is discussed elsewhere (4).

Assembly; experimental procedure. The final assembly used in lung volume and lung clearance studies is shown in the upper portion of Figure 5, together with the slight modification (lower diagram) when nitrogen retention during the breathing of air is to be measured. The assembly is essentially similar to that used in the end-point sampling method except for the fact that the sampling tube is connected to the evacuated lucite distributor and multiple reservoir system already described. The sampling tube indicated in the oxygen line is for determining the composition of the supply oxygen from time to time and for establishing the absence of air leaks.

The procedure is also similar to that already described, save for changes necessitated by serial sampling. The sampling procedure involves counting of the number of breaths of oxygen, rapid manual operation of the stopcocks in the distributor assembly during the appropriate *inspiration*, and simultaneous operation of an electric signal which records the spirometer volume on the ink record at the instant of sampling. The technic needs to be rehearsed a few times.

SUMMARY

The extension of open-circuit methods of measuring lung volumes to a study of lung clearance rates requires certain physical modifications which are enumerated above (see also page 679). The necessary modifications have been embodied in two experimental assemblies and procedures referred to as "end-point sampling" and "serial sampling."

The assembly designed for end-point sampling experiments is composed of standard pieces of equipment, slightly modified. The method, although capable of considerable accuracy, is laborious.

The assembly designed for serial sampling requires a specially designed gasometer of small internal and external dead space, equipped with means for rapid mixing of the expired gases and with attachments for rapid sampling. With such an assembly, lung clearance curves can be obtained in about one-tenth of the time required by the end-point sampling method. A pivoted type gasometer designed and built for use in the serial sampling

apparatus, but also suitable for standard spirometric studies by open-circuit or closed-circuit methods, is described.

Experimental procedures are given for the study of pulmonary clearance curves by the two methods.

OBSERVATIONS ON THE PROTEOLYTIC ACTIVITY *IN VITRO* AT NEUTRAL REACTION OF GASTRIC JUICE FROM PATIENTS WITH SPRUE¹

By HERBERT J. FOX²

(From the Department of Medicine, Duke University Medical School and Hospital, Durham, N. C.)

(Received for publication December 22, 1948)

Previous investigators (1) have demonstrated the presence in normal human gastric juice of a protease which is active at neutral reaction. Certain properties were exhibited which distinguished the enzyme from pepsin and trypsin. Subsequent studies (2-4) showed that the protease and the so-called intrinsic factor of Castle possessed certain identical properties: both are removed by adsorption with Lloyd's reagent, both are unable to penetrate a semi-permeable membrane, they are not destroyed by Berkefeld filtration or exposure to alkali, but are destroyed by exposure to heat and are inhibited by an environment more acid than pH 3.5. Furthermore, it was found that this protease activity was absent or greatly diminished in patients with Addisonian pernicious anemia, but was normal in patients with pernicious tapeworm anemia.

The pathogenesis of the macrocytic anemia in sprue has aroused much speculation. Because it seemed important to determine whether or not the intrinsic factor was contained in the gastric juice of this disease, and because the gastric protease which is active at neutral reaction may be identical with Castle's intrinsic factor, it was decided to measure gastric protease activity at neutral reaction in sprue.

METHODS

The method was similar to that previously described (1), except for modifications noted below. Gastric juice was collected free from bile after stimulation with histamine and promptly filtered through gauze. The juice was brought to pH 10 with sodium hydroxide and kept for 30 minutes at 40° C. after which it was brought to pH 7.4. To 50 ml. of such materials were added 50 ml. of a 1 per cent neutral casein solution, the mixture ad-

justed to pH 7.4 and 2 ml. of toluol added. The mixture was incubated at 37.5° C for 24 hours, the pH remaining constant. The procedures used for the formol titration of amino nitrogen and for the determination of total filtrable nitrogen were those previously described (1, 2). Samples of the digests were taken immediately, at four hours, and 24 hours for formol titration. At the same time intervals, samples were removed and analyzed for the total amount of nitrogen not precipitable by 10 per cent trichloroacetic acid. The amount of total filtrable nitrogen and of amino nitrogen produced in 24 hours was calculated from these determinations. Proteolytic activity was judged from increases in filtrable nitrogen in milligrams per 100 ml. digest. The absence of active trypsin was shown by the lack of a significant increase in amino nitrogen.

RESULTS

From a large number of experiments the following facts were confirmed:

(1). *The effect of incubation of normal human gastric juice with casein solution at pH 7.4.* The fasting contents from normal subjects were removed and discarded. Histamine phosphate 0.5 mgm. was injected intramuscularly and the gastric secretion collected during the next hour. Certain physical changes occurred when such gastric juice was incubated with an equal quantity of 1 per cent casein solution at pH 7.4. The digestion mixtures became chalky white. The trichloroacetic acid filtrates from these serial samples showed progressive increases in turbidity. Increases in the total nitrogen in the trichloroacetic acid filtrates occurred along with these physical changes.

Peptic activity is not manifest at neutral reactions, and above pH 8 pepsin is destroyed rapidly by OH ions. Furthermore, it has been shown (5) that exposure to alkali at pH 10 at 40° C for 30 minutes destroys from 70 to 80 per cent of trypsin in solution. There was no significant increase in amino nitrogen in our experiments. This suggests that trypsin and other crepsin-like enzymes of duodenal origin did not account for increase in

¹ Aided by grants from the John and Mary R. Markle Foundation, and the Duke University Research Fund.

² Associate in Medicine, Department of Medicine, Duke Medical School.

filtrable nitrogen. The results of ten experiments on normal controls, which agree with previous reports, are shown in Table I.

That infection may have an inhibitory effect is suggested from determinations made on gastric juice obtained from patients at the time of an acute respiratory illness and following convalescence. The results of two such experiments are included in Table I. This would indicate that the gastric protease is inhibited during an acute illness and that the inhibitory factor disappears following recovery.

(2). *The effect of incubation of human gastric juice, collected from sprue, with casein solution at pH 7.4.* Collections of gastric juice from sprue patients and treatment with alkali before mixing with casein for digestion were performed in a fashion similar to that used on normal controls. The results of 11 of these experiments on sprue are shown in Table II. The gastric juice obtained from cases of sprue in remission showed progressive increases in filtrable nitrogen which compared closely to results in normal controls. On the other hand, the gastric juice from cases of sprue in relapse, with characteristic diarrhea, meteorism, steatorrhea, weight loss, glossitis, and anemia, showed a greatly diminished production of total filtrable nitrogen. Also, it is noteworthy that there was no significant increase in amino nitro-

* Samples of gastric juice 31a and 31b were obtained from the same donor. Sample 31b was obtained five months later during remission.

† Case 37 had a-chlorhydria.

gen. Experiments 31a and 31b noted in Table II were performed on the same patient during a period of relapse and remission respectively. These data would indicate that the gastric protease is distinguishably less during the relapse stage.

DISCUSSION

In the majority of sprue patients, gastric secretion was obtained without difficulty in a one-hour period. During the stage of severe relapse there was usually hypochlorhydria and a marked reduction in rate of secretion and in proteolytic activity at neutral reaction. Such patients were observed again and tests repeated six months after treatment had produced remission, and they then showed a return to normal in all these functions. These data suggest that intrinsic factor activity may also be reduced in the gastric secretions of persons with sprue in relapse.

Attempts were made to do a biologic assay of the gastric secretions from these patients in relapse to determine the presence or absence of intrinsic factor. Our efforts to collect sufficient gastric juice for daily feeding experiments failed. However, previous investigators (6) have performed a biologic assay on gastric secretions from a case of sprue. Apparently, they demonstrated the absence of intrinsic factor from the gastric contents of a

case of sprue in relapse by feeding daily collections of gastric juice mixed with beef muscle to a case of Addisonian pernicious anemia.

It has been stated (7) that the deficiency in sprue may come about in a number of ways, among which are (1) a deficiency of extrinsic factor, (2) a defect of gastric digestion resulting from lack of intrinsic factor, and (3) defective absorption from the intestinal tract.

The mal-absorption from the small intestine in patients during relapse can be demonstrated with great frequency and certainly is a major cause of the sprue syndrome. Defective absorption of fats, fat-soluble vitamins, calcium, and carbohydrates can be commonly demonstrated. Patients with severe diarrhea will also show faulty assimilation of protein.

Dietary histories on our sprue patients have not shown any correlation between the ingestion of meat products, or other sources of extrinsic factor, and the incidence of anemia. When fed adequate amounts of beef muscle, the patients in relapse failed to obtain a remission. Subsequently, they made a satisfactory response to injectable liver extract or folic acid.

The data presented in this paper support the concept that a defect in gastric digestion may be important to the occurrence of macrocytic anemia in sprue; though whether such a defect is primary or secondary to gastro-intestinal mal-absorption and chronic debility can not be ascertained. Data reported here show that acute infection can lower the value of the proteolytic activity at neutral reaction to a very low level.

The fact that the anemia of sprue is macrocytic and improved by liver does not mean that a primary deficiency of gastric origin is present. This is well shown by the pernicious tapeworm anemia.

It can only be said that the protease activity of the gastric juice is lessened in sprue in relapse and normal in remission.

CONCLUSIONS

1. When equal quantities of normal human gastric juice and 1 per cent casein solution are incubated at 37.5° C and pH 7.4, there is a progressive increase in filtrable nitrogenous substances. The proteolysis was not considered to result from pepsin because the activity was maximal at pH 7.4. Also, since there was no significant increase

in amino nitrogen within 24 hours, together with the persistent increase in total filtrable nitrogen after exposure to pH 10, it is considered that the proteolysis was not due to trypsin.

2. The proteolytic activity of the gastric enzyme at neutral reaction, is present to a normal degree in cases of sprue in remission. It is greatly diminished in cases of sprue in relapse. The absence of proteolytic activity in cases of pernicious anemia suggests that the deficiency of intrinsic factor so characteristic of pernicious anemia, may be present in sprue in relapse.

3. In two non-anemic normal subjects, it appears that infection inhibited this type of proteolysis to a considerable degree.

SODIUM AND CHLORIDE DEPLETION IN ACUTE PORPHYRIA WITH REFERENCE TO THE STATUS OF ADRENAL CORTICAL FUNCTION

By F. T. G. PRUNTY

(From the Department of Chemical Pathology, St. Thomas's Hospital Medical School,
London, England)

(Received for publication December 27, 1948)

INTRODUCTION

The fact that depletion of sodium and of chloride may occur in acute porphyria, in the absence of alkalosis due to vomiting, has recently been noted independently by Abrahams, Gavey and MacLagan (1) and by Linder (2). These authors suggested that a possible basis for this deficiency was that of adrenal cortical failure, but the response of their two patients to substitution therapy with cortical hormones does not appear to have given unequivocal evidence for this hypothesis.

The present paper presents an attempt to explore this question in further detail. The plan of investigation falls under two headings: firstly to study the function of the adrenal cortex during the height of an attack of acute porphyria and secondly to observe the response to desoxycorticosterone administration in greater detail. Prunty, Forsham and Thorn (3) have recently indicated that the elucidation of adrenal cortical function with respect to its relation to electrolyte metabolism is a complex matter, whereas the functional production of the 11-oxy-steroid group of hormones is more easily assessable by urine analysis and the use of the response to purified adrenocorticotrophic hormone. The severity of the illness of the patient under observation was considered a contraindication precluding the use of the deprivation test of Cutler, Power and Wilder (4).

METHODS

The patient (Case 1) was confined to bed during the first 80 days of observation. During the period of electrolyte study she was maintained on a light diet, kept as constant as possible, with the addition of 7 gm. of sodium chloride daily, the major portion of which was given orally as half normal saline. Urine was collected daily under toluene and analysed the day of completing the collection. The methods of analysis used were as follows. Sodium by the method of Butler and Tuthill (5);

chloride by the iodometric method of Van Slyke and Hiller (6); potassium by King's method (7); carbon dioxide combining power by the technique of Peters and Van Slyke (8). Total base in serum was estimated by electro dialysis (Malm [9]). "Neutral reducing steroids" in the urine were determined by the author's modification of the method of Talbot *et al.* (10),¹ and 17-ketosteroids by that of Callow, Callow and Emmens (11), using a correction equation for interfering chromogens. The adrenocorticotrophic hormone test for adrenal cortical reserve has been fully described by Forsham *et al.* (12). Total urine porphyrin was estimated by adsorption on a calcium phosphate precipitate followed by solution in hydrochloric acid as described by Sveinsson, Rimington and Barnes (13), the final assay of porphyrin being carried out in the fluorimeter.

OBSERVATIONS

Plasma electrolyte changes

The trend of the alterations found in the plasma electrolytes is indicated in Table I, and Figures 1 and 2. At the commencement of the period of observation the patient was receiving potassium citrate, 2.7 gm. per diem, on account of mild urinary symptoms. At this time (15th day) there was a moderate deficiency of sodium and of chloride, the values being 125 and 86 MEq. per l. respectively. The carbon dioxide combining power was normal (30.4 MEq. per l.). It will also be noted that there was a moderate elevation of blood pressure, a characteristic of this disease. On the 19th day potassium citrate was withdrawn and on the 20th day a six-day period of desoxycorticosterone acetate administration commenced. This was given in two doses per day of 5 mgm. each intramuscularly. On the fifth day of desoxycorticosterone administration the serum potassium had

¹ The determination of "neutral reducing steroids" in the urine is thought to bear a relation to the endogenous 11-oxygenated corticosteroid production. The reducing substances in the urine have hitherto sometimes been loosely termed "11-oxysteroids."

fallen as low as 1.9 MEq. per l. There was no definite electrocardiographic evidence of potassium deficiency, but there was an increase of muscle pain suggesting the onset of the potassium deficiency syndrome, and it was decided that the desoxycorticosterone should be stopped after a further 24 hours. On cessation of desoxycorticosterone administration the serum potassium was still as low as 2.1 MEq. per l., whereas there had

only been a slight rise in serum sodium to 129 MEq. per l. and in chloride to 89 MEq. per l. The behaviour of the blood pressure was unexpected in that a fall occurred from 165/120 to 135/88 during this period and subsequently rose again.

The patient was then maintained for ten days on sodium chloride without adjuvant therapy, during which there was slight improvement in the

FIG. 1. THE EFFECT OF DESOXYCORTICOSTERONE AND OF POTASSIUM ON THE SERUM ELECTROLYTES (CASE 1)

EFFECT OF D. O. C. A. IN ACUTE PORPHYRIA.

FIG. 2. THE EFFECT OF DESOXYCORTICOSTERONE ON SERUM CHLORIDE AND BLOOD PRESSURE (CASE 1)

sodium and chloride with a persistently low potassium. Potassium chloride was given in 2 gm. doses daily from the 36th day and thereafter there was a marked improvement with respect to potassium, chloride and sodium. This corresponded to a period of clinical improvement. The changes in the carbon dioxide combining power were minimal throughout these periods.

Excretion of urine chloride

It will be seen from Table II that in spite of moderate hypochloreaemia at the beginning of observation the urine chloride excretion amounted

to as much as 168 MEq. per day. It remained considerable throughout the period of study.

Excretion of "neutral reducing steroids" and response to adrenocorticotrophin

On the 18th and 21st days the excretions of urinary "neutral reducing steroids" were observed to be 0.62 and 0.54 mgm. per day, about twice the normal figure. At the 90th day this excretion had fallen to normal values and there was a small fall in 17-ketosteroid excretion which remained at low normal values (Figure 3).

On the 16th day a single dose of 24 mgm. adrenocorticotrophin² was given intramuscularly. This elicited after four hours a normal fall in circulating eosinophils of 91 per cent (Figure 3). The test was repeated on the 97th day and produced a smaller decrease, amounting to 60 per cent. It should be noted that in the first case the total fasting eosinophil count was only 59 per

TABLE II
Urine excretion of chloride (Case 1)

c.mm., whereas in the second case it had risen to 236 per c.mm., thus behaving inversely to the excretion of "neutral reducing steroids." The data concerning uric acid metabolism show that in the initial test the uric acid excretion was high, the fasting uric acid/creatinine ratio being 0.71. In the second test the excretion had fallen to normal, the ratio being 0.46. On the first occasion the response in urinary excretion of uric acid to adrenocorticotrophin was small, but this was offset by a sharp rise of 17 per cent in the plasma uric acid level. These events occurred at a time when the blood urea was elevated to 51 mgm. per 100 ml. On the second occasion the response of urine uric acid excretion was on the low side of normal, the urine uric acid/creatinine ratio rising from 0.46 to 0.69 after adrenocorticotrophin. In this test the alteration in plasma uric acid was minimal.

The interpretation of these changes would appear to be as follows (Forsham *et al.* [12]).

1. In the early period there was increased adrenocortical activity suggested by:

(a) Increased excretion of "neutral reducing steroids" in the urine.

(b) High fasting urine uric acid/creatinine ratio.

(c) Low fasting eosinophil count.

2. In the early period there was adequate adrenal cortical reserve function, shown by:

(a) Normal fall in eosinophil count after adrenocorticotrophin.

(b) A sharp rise in the plasma uric acid level, associated with evidence of decreased renal function and absence of increase in urine uric acid excretion at a time when uric acid excretion was already enhanced.

3. In the later period, after complete subsidence

FIG. 3. "NEUTRAL REDUCING STEROID" EXCRETION AND RESPONSE TO ADRENOCORTICOTROPHIN (CASE 1)

FIG. 4. ADRENAL CORTEX (CASE 3) $\times 180$

of the attack of porphyria, the adrenal cortical activity had returned to normal, indicated by:

(a) The normal excretion of "neutral reducing steroids."

(b) The fall to normal of the fasting urine uric acid/creatinine ratio.

(c) The increase in the fasting eosinophil count.

4. In the later period there was still an adequate reserve in adrenal cortical function, shown by:

(a) Normal fall in eosinophil count after adrenocorticotrophin.

(b) Low normal response in the urine uric acid/creatinine ratio to adrenocorticotrophin.

Postmortem findings in the adrenals in Cases 2 and 3

Examination of the adrenals from two further cases of acute porphyria (Cases 2 and 3) gave evidence of cortical hypertrophy. In Case 2 the left adrenal weighed 7 gm. and in Case 3 the total weight of both adrenals was 16 gm. Histological examination of sections stained with haematoxylin and eosin showed hypertrophy of the cortical tissue, and the cortical widths in Cases 2 and 3 were approximately 2 and 4 mm., respectively. In addition a greater number of cortical cells, especially in the fasciculata, showed a well-stained uniform cytoplasm and absence of lipoid

vacuolation of the cytoplasm than is seen in the normal cortex (Figure 4). There is also evidence of increased capillary dilatation in these areas.

FIG. 5. KIDNEY, HAEMATOXYLIN AND EOSIN $\times 150$ (CASE 4)

Postmortem findings in the kidneys in cases of acute porphyria

Histological examination of the kidneys from Cases 2, 3 and 4 showed similar appearances. There was congestion of the capillaries and Cases 2 and 3 particularly showed some swelling of the capsular epithelium with the presence of eosinophilic material within the capsular space (Figure 5). The convoluted tubules and particularly the second convoluted tubules, showed severe cloudy swelling and atrophic changes in places. The lumina of some of the tubules contained epithelial debris. The nuclei showed varying degrees of pyknosis which in places was marked (Figure 6, Case 3).

Ultraviolet microscopy of the material from Case 2 showed a ring of red fluorescence in many of the tubules and a diffuse reddish fluorescence among necrotic epithelial elements contained within the tubules. In Case 4 there was a fairly intense red fluorescence in the convoluted tubule cells and in the debris within the tubules.

DISCUSSION

The responses of fall in eosinophils and of increased uric acid excretion to adrenocorticotrophin have been shown by Forsham *et al.* (12) to be due primarily to 11-oxy-steroid secretion by an adrenal cortex capable of stimulation. By these criteria Case 1 would appear to have an adequate adrenal cortical reserve, both during the height of the attack of porphyria and after its cessation. The increased excretion of "neutral reducing steroids" in the urine during the acute phase is suggestive of increased adrenal cortical activity and is supported by finding some elevation of the fasting blood sugar at the conclusion of the adrenocorticotrophin test. Such a response to the adrenal is typical of the "alarm reaction" of Selye (14) to non-specific somatic trauma, and may occur in the course of any acute episode in a disease process.

The question of a parallel increase of desoxycorticosterone-like activity on the part of the adrenal under such conditions is not settled, but it is probable that the part played by the adrenal in the "alarm reaction" is mediated through the anterior pituitary (Selye [14], Long [15]) and there is evidence suggesting that anterior pitui-

FIG. 6. KIDNEY, HAEMATOXYLIN AND EOSIN (CASE 3)

tary adrenocorticotrophin can under certain conditions stimulate increased desoxycorticosterone-like activity (Prunty *et al.* [3]). The response of Case 1 to desoxycorticosterone was investigated with the idea that if endogenous desoxycorticosterone deficiency existed a dramatic response should be obtained as observed by Loeb *et al.* (16) and by Thorn *et al.* (17) in Addison's disease. On the other hand, if endogenous production was adequate the response would be less dramatic. The observed response was poor especially when the potentiating effect of potassium withdrawal is also considered. The most marked effect appears to have been in decreasing an already low serum potassium, which latter in itself is unlikely in the presence of endogenous deficiency of desoxycorticosterone. In the case reported by Abrahams *et al.* (1) the serum potassium was also below, rather than above, normal. The observation of a fall in blood pressure during the administration of desoxycorticosterone is an unusual one, and not a typical response. The effect of desoxycorticosterone in increasing chloride excretion has so far only been observed in

FIG. 7. ADRENAL CORTEX FROM A CASE OF CUSHING'S SYNDROME, EXCRETING 8.2 MG. OF "NEUTRAL REDUCING STEROIDS" PER DIEM (FOR COMPARISON)

man under conditions where available desoxycorticosterone is excessive, either from excessive administration (Zierler and Lilienthal [18]) or in Cushing's syndrome (Soffer *et al.* [19]). It was also found that improvement in the state of serum electrolytes and of the patient's general condition continued and even became more marked when potassium chloride was subsequently given.

The postmortem state of the adrenals in Case 2 and Case 3 suggests increased adrenal cortical activity. Adrenal hypertrophy also appears to have been present in the case of Abrahams *et al.* (1). The adrenals of these cases may be compared with the adrenal cortex from a man with Cushing's syndrome excretion up to 8.2 mgm. per day of "neutral reducing steroids" (Figure 7). The findings in these glands, in the light of evidence of increased cortical activity in Case 1, are compatible with those of Rogers and Williams (20).

If the sodium and chloride deficiency observed is not due to adrenal failure, some other explana-

tion must be sought. Examination of the kidneys from Cases 2, 3 and 4 shows mild changes reminiscent of those seen in the so-called "renal anoxia" syndrome described by Macgrath, Harvard and Parsons (21), or perhaps better termed "lower nephron nephrosis" by Lucké (22). The renal changes have been well described by Darmady *et al.* (23). In this syndrome failure by the kidney to retain chloride has been found to occur by Humphrey and Jones (24), and even potassium deficiency can apparently occur (Bywaters and Stead [25]). It has been shown by Thorn, Koepf and Clinton (26) that sodium and chloride retention is not induced by desoxycorticosterone when certain types of renal lesion are present, and where marked depletion of these ions may be found (Peters, Wakeman and Lee [27]). A mild degree of non-protein nitrogen retention also frequently occurs in porphyria and was observed in Cases 1, 2 and 4. The possibility that the renal tubules in Case 1 may have been involved in pyelonephritic lesions must be also taken into account. Pyelonephritis was observed to occur in the case of Abrahams *et al.* (1). It is clear that further investigations of these points are required with more attention to the functional renal pathology.

SUMMARY

1. A phase of decreased plasma sodium and chloride has been studied in acute porphyria. This reacted poorly to administration of desoxycorticosterone acetate.

2. Data concerning the eosinophil counts, uric acid excretion and "neutral reducing steroids" excretion indicated increased adrenal activity during the acute phase of the disease. The response by the adrenal to adrenocorticotrophin stimulation showed an adequate adrenal cortical reserve function during the acute phase and in convalescence.

3. From examination of adrenals of cases of acute porphyria it is evident that cortical hypertrophy can occur and there is histological evidence that secretory activity may be increased.

4. In the light of present knowledge the correlation of the various phases of adrenal cortical activity are discussed and it is concluded that the disordered electrolyte metabolism is not primarily adrenal in origin. Abnormalities present in histological section of the kidneys suggest the

necessity for further investigation of renal function in this disease.

APPENDIX

Case notes

Case 1. A 42-year-old woman complained that for nine days she had suffered from anorexia and nausea. She was an orphan, and had two healthy children. Since an operation for prolapse eight years previously she had had attacks of cystitis. For a week there had been marked asthenia and several attacks of vomiting with small quantities of vomitus, and she complained of an aching pain in the lower abdomen. The attack coincided with one of her menstrual periods which were normal. She had noticed nocturia. The patient was a dark-haired individual with some generalised increased pigmentation and mild facial hirsuties. There was marked tenderness in both inguinal fossae, but no guarding, and constipation was severe. Blood pressure was 150/90, pulse rate 100 and temperature ranging up to 99° F. The urine contained a trace of albumin and a few pus cells of which 80 per cent were polymorphs. The blood urea was 44 mgm. per 100 ml. She was given potassium citrate on account of her urinary symptoms.

After seven days penicillin therapy was commenced but without effect. After 13 days of increased pain and developing rigidity in the lower abdomen exploratory laparotomy was carried out without significant findings. The patient had become mentally poorly co-operative and was slightly hallucinated.

Her urine then was shown to contain porphobilinogen and uroporphyrin and the diagnosis of acute porphyria was established, the uroporphyrin excretion ranging from 12 to 35 mgm. per day. (A study of the porphyrin excretion is being fully reported elsewhere [McSwiney, Nicholas and Prunty, 1949] [28].)

On the 15th day her blood pressure had risen to 160/115 and the pulse rate varied between 120 and 130 for the following three weeks. The plasma protein was 5.4 gm. per cent, albumin 3.3 gm. per cent, globulin plus fibrinogen 2.1 gm. per cent. Serum cholesterol was 222 mgm. per cent with 68 per cent ester; alkaline phosphatase 2.4 units, thymol turbidity 4 units; blood urea 51 mgm. per cent and icteric index 4 units. On the 16th day the urobilinogen excretion was 2.9 mgm. per day, and 10.4 mgm. per day on the 28th day. It fell to less than 1 mgm. per day from the 22nd day onwards. At the conclusion of the adrenocorticotrophin test on the 16th day and after 18 hours' fast, the blood sugar was 131 mgm. per cent, but glycosuria was never found. Values for serum electrolytes are recorded in Table I.

Potassium citrate was withdrawn on the 18th day and desoxycorticosterone acetate 5 mgm. b.d. given intramuscularly from the 20th to 25th days inclusive, and she was receiving 7 gm. of added sodium chloride. At the end of this period of six days she complained of increasing widespread muscle pain and a constrictive feeling in the chest. There was a generalised fine somatic tremor. The electrocardiogram was interpreted as being within

normal limits on two occasions, but reading was difficult on account of the tremor. Since the patient's condition had apparently deteriorated and the potassium level was so low (Table I) D.O.C.A. was withdrawn.

On the 29th day the plasma protein was 5.9 gm. per cent, albumin 3.0 gm. per cent; serum cholesterol 311 mgm. per cent, 64 per cent being ester; alkaline phosphatase 2 units; icteric index 5 units. There was a *B. coli* bacilluria which failed to improve with penicillin therapy.

On the 36th day she was given potassium chloride 2 gm. daily in addition to the sodium chloride. From this time she started to improve clinically and the pulse rate gradually returned to normal in the following five weeks. At the end of this period she had greatly improved, the blood pressure had fallen to 130/60, and urea clearance was 75 per cent of normal. The *B. coli* bacilluria was cleared up with mandelate therapy. After a further four weeks she was discharged well.

Case 2. A girl aged 16 was admitted to hospital with convulsions after a week's acute abdominal pain. Pulse rate was 110, temperature 100.5° and blood pressure 120/80. Blood urea was 43 mgm. per cent, plasma protein 7.5 gm. per cent, albumin 3.4 gm. per cent. Urine urobilinogen two plus. The urine contained porphobilinogen, and uroporphyrin amounting to 15 mgm. per day. The attack subsided in three weeks.

Six months later the patient returned with abdominal pain, soon after the onset of which menstruation commenced. After two weeks ascending paralysis appeared and the patient ultimately died of bronchopneumonia and intercostal paralysis. Investigations during the attack showed 26,000 white cells; blood urea 62 mgm. per cent, plasma protein 6.5 gm. per cent, albumin 3.2 gm. per cent. There was a slight increase of urine urobilinogen and an occasional granular cast. The urine uroporphyrin excretion ranged up to 68 mgm. per day.

The chief postmortem findings were areas of focal necrosis in the liver which was shown to contain uroporphyrin by ultraviolet microscopy and analysis. It also contained porphobilinogen. The renal and adrenal findings are described above. Detailed investigations of the case have already been reported. (Prunty [29].)

Case 3. A man aged 20 complained of marked asthenia for several weeks. Six months previously he had an attack of paralysis accompanied by a dark urine, and three months previously an attack of abdominal pain with similar urine.

During the present attack the pain was generalised with tenderness in the iliac fossae. There was slight conjunctival icterus. After the onset of mild paralytic symptoms he died suddenly in ten days. The serum sodium was 126 MEq. per l. and blood urea 34 mgm. per cent nine days before he died. Porphobilinogen and porphobilin were present in the specimen of urine examined and a moderate amount of uroporphyrin as the zinc metal complex.

At autopsy the myocardium was found to be thin, but otherwise normal. The liver showed areas suggestive of early focal necrosis. The hepatic cells contained numerous brownish pigment granules, particularly in the cen-

tral portion of the lobules. The adrenals and kidneys have been described above.

Case 4. A man aged 26 for two months noticed a darkening in the colour of his urine. At birth a meningocele was present. He was admitted to hospital with a diagnosis of intestinal obstruction for two days. Constipation was complete. He was in shock with a very low blood pressure, pulse 140, and temperature 101° F. The blood contained 18,500 white cells; N.P.N. 66 mgm. per cent, carbon dioxide combining power 41 MEq. per l., chloride 88 MEq. per l. The urine had a specific gravity of 1020, no albumin, but hyaline casts and unidentified brown crystals were present. There was a great deal of porphobilin present in the specimen of urine examined, with much porphyrin metal complex which could not be further identified with the amount of material available. There was a two plus reaction for urobilinogen.

The patient died at the end of a week and autopsy showed congenital absence of the left kidney with double renal pelvis and ureter on the right. There was extreme gut distention and much fluid present. The liver appeared normal. Histologically the liver showed the presence of numerous non-iron staining brownish granules in the liver cells. Ultraviolet microscopy revealed intense red fluorescence in these areas. The pigment appeared to be concentrated particularly in the cells in the central portions of the lobules, particularly about the central vein. The parenchyma in the centres of some of the lobules showed early degenerative changes. The kidney is commented upon in the text above.

I am indebted to Drs. Adams and Harewood Little for material from Cases 3 and 4.

TREATMENT OF NEPHROSIS WITH CONCENTRATED HUMAN SERUM ALBUMIN. I. EFFECTS ON THE PROTEINS OF BODY FLUIDS¹

By JOHN A. LUETSCHER, JR.,² ALASTAIR D. HALL, AND VIRGINIA L. KREMER

(From the Department of Medicine, The Johns Hopkins University and Hospital, Baltimore)

(Received for publication December 30, 1948)

The preparation of a pure, concentrated human serum albumin by Cohn and his associates (1) offers a unique opportunity for the study and treatment of patients with a deficiency of serum albumin. The homogeneity of this material permits the tracing of the administered protein (2), while the infrequency of untoward reactions on the patient and the freedom from risk of homologous serum jaundice allow the use of albumin in cases in which the physician would hesitate to administer whole plasma or plasma substitutes (3-5).

The severe deficiency of albumin in the nephrotic syndrome presents a strong indication for albumin therapy, but treatment with albumin has produced quite variable effects on hypoproteinemias and edema (4-9). The variability of clinical and chemical response in different patients and in the same patient at different times led us to examine in detail the effects of the administration of concentrated human serum albumin to patients with the nephrotic syndrome. The results call for a re-examination of some of the basic assumptions concerning the hypoproteinemia and edema of nephrosis.

PATIENTS

Thirteen patients with the characteristic features of the nephrotic syndrome have been treated. No patients with marked hypertension or renal insufficiency were included.

The patients were put to bed and given a diet calculated to contain protein, 1 gram/kg. and sodium 0.5 m.eq./kg. per day, with fluids ad lib. When the fasting weight

became stationary for three or more successive days, treatment with concentrated human serum albumin in 25% solution was begun. Albumin was administered through a 20 or 21 gauge needle, at a rate of 25 grams in 40 to 60 minutes.

Twenty courses of albumin therapy have been given, varying from three to six days in length. The usual dosage was 50 grams per day, but daily dosage was modified in four cases to meet individual problems. Only 25 grams per day were given to one older patient as a precaution against possible cardiovascular complications. Dosage was reduced to 25 grams per day for two women who complained of severe headache after larger doses. Seventy-five grams per day were given to one patient in whom 50 grams had failed to induce diuresis, but the only additional effect was an increased proteinuria.

The duration of treatment was guided by the effects. In the early cases, we received the impression that the maximal diuresis occurred in the first few days of treatment, so that if diuresis failed to appear in three to five days, treatment was stopped. If a good diuresis appeared, treatment was continued until the weight became stationary and/or edema disappeared. These principles were tentative and were determined to some extent by the availability of albumin at that particular time.

METHODS

These have been described in an earlier report (2). The following minor changes have been made. No attempt has been made to determine the plasma volume with T-1824 when fasting serum was visibly lipemic. Plasma protein concentration was determined by nitrogen content, which has also been used for albumin determination by sodium sulfate fractionation. Albumin concentration, measured by electrophoresis, cannot be calculated from the total protein concentration measured by nitrogen content, since the refractive index of lipid-rich plasma is higher than expected from its nitrogen content (10, 11). Since the electrophoretic analysis measures the proportion of colloid refractive increment contributed to serum by albumin, this percentage has been applied to the total colloid refractive increment of the serum to ascertain the refractive increment contributed by albumin. As the specific refractive increment of albumin is known, the albumin concentration can be calculated. This calculation yields a value for albumin concentration which is lower than the value obtained from the sodium sulfate fraction, which is known to be contaminated with globulin. The difference between the two values for albumin concentra-

¹ This investigation was supported by a research grant from the Division of Research Grants and Fellowships of the National Institute of Health, U. S. Public Health Service.

The concentrated human serum albumin used in this study was made available in the largest part by the American Red Cross, and in smaller amounts for specific cases by the Sharp and Dohme Company and by the U. S. Navy.

² Present address: Stanford University Hospitals, San Francisco 15, California.

tion was constant in the same individual from time to time, but among eight different patients of this series the difference varied from 0.2 to 1.0 gram per 100 cc.

RESULTS

1. *Plasma volume.* Following each injection of concentrated albumin, there was a rapid expansion of plasma volume (Figure 1). The dilution of the blood was often clearly visible as lipemia and hemoglobin concentration declined. Measurement of the plasma volume with blue dye, T-1824, confirmed the hemodilution when the plasma was clear. If the plasma was even slightly lipemic, dilution increased light transmission very greatly, giving further evidence of the dilution of the blood but making the direct determination of dye impossible. The concentration of globulins in the plasma decreased after each injection of albumin (Figure 2). The concentrations of the globulins and of hemoglobin rose again in the intervals between injections.

The various methods agreed on the large magnitude of the increase of volume. The data obtained by several methods in one patient are presented in Figure 3. Volumes based on the fall

in hematocrit probably exaggerated the extent of the changes. Measurement of the hemoglobin concentration indicated a smaller change in plasma volume. The dilution of the blue dye T-1824 was also less than the dilution of the blood cell volume. Dilution of the plasma globulin (determined by electrophoresis) corresponded reasonably well with the other determinations. In calculations involving plasma volume, the dilution of T-1824 has been used.

Observation of the patient confirmed the increased blood volume. After each injection, the veins of the neck became fuller as the venous pressure rose a few centimeters of water. Transitory increases in pulse rate and blood pressure were common. A sensation of fullness in the head and neck was sometimes noted by the patient. Dyspnea sometimes followed the administration of albumin when the vital capacity was seriously reduced by pleural effusions and ascites.

When 50 to 75 grams of albumin were given daily, there was considerable individual variation in the duration of the effect on plasma volume (Figure 1). In some cases, the increase in volume was sustained for many hours. Subsequent in-

FIG. 1. EFFECT OF INTRAVENOUS ADMINISTRATION OF ALBUMIN ON THE PLASMA VOLUME

All volumes are related to the initial volume taken as unity. The heavy outlines show the range, and the broken line gives the average of measurements during 12 courses of treatment of nine patients. Note the large increase in plasma volume after each dose of 100 cc. of 25% solution of albumin.

FIG. 2. EFFECTS OF INTRAVENOUS ADMINISTRATION OF ALBUMIN ON THE CONCENTRATIONS OF PLASMA PROTEIN, ALBUMIN, AND GLOBULINS

Data are from 14 courses of treatment of 11 patients. The heavy outlines give the range, and the middle lines the average of the individual cases. Each injection was followed by an increase in the plasma albumin concentration, while the globulin concentration fell. Treatment had little effect on the total plasma protein concentration in the ten instances whose average is shown by the broken line, but in four patients, there was a definite increase in the protein concentration, indicated by the dotted line. All of these four patients were free of edema at the end of treatment.

jections on the same day produced further increases, and the volume did not return to the base line overnight (Figure 4). In Case 1, a maximum was reached on the second day at a volume nearly double the control levels (Figure 5). In other cases, the maximum was reached more slowly. In a few instances, the plasma volume returned rapidly toward its usual level, and cumulative increases in volume on successive days were small or absent (Figure 1).

2. *Concentration of albumin and globulins in plasma.* In most of the patients studied, the concentration of albumin in the plasma was increased

most strikingly on the first two days of therapy (Table I). Subsequent injections produced much smaller changes in the concentration of plasma albumin, which fell quickly when therapy was stopped (Figure 2). A cumulative increase in albumin concentration beyond the first few days is possible when proteinuria is minimal and when diuresis follows (Table I).

The increased albumin concentration was reflected in a parallel rise in colloid osmotic activity of the plasma (Figure 5).

The change in the total protein concentration was less striking and frequently was negligible (Table I, Figure 2). When concentrated albumin solutions are injected intravenously, the added albumin draws into the plasma a large volume of extracellular fluid. The plasma globulins are diluted, and the concentrations of the various electrophoretic fractions fall in a uniform fashion as the albumin concentration rises. Since albumin has a higher osmotic activity than most of the proteins of nephrotic plasma, more water per gram of protein may enter the plasma than was originally present. Thus the total protein concentration may decrease after an injection of albumin, even though the osmotic activity of the plasma is increased by the rise in concentration of albumin (Figure 5). On later days of treatment, the total protein concentration tended to rise slowly, but there was consider-

FIG. 3. CHANGES IN PLASMA VOLUME CALCULATED FROM DILUTION OF DYE, HEMATOCRIT, HEMOGLOBIN AND GLOBULIN, IN A PATIENT RECEIVING ALBUMIN (CASE 1)

The initial plasma volume was determined with the blue dye T-1824. Subsequent changes were calculated on the basis of dye (square), hematocrit (solid circle), total hemoglobin determined as cyanmethemoglobin (open circle), and globulin determined by electrophoresis (cross). All data agree on the large increases in volume. The hematocrit tends to exaggerate the change.

able variation from patient to patient. Two factors which influenced the changes in plasma protein and albumin concentration were variations in edema and the loss of albumin from the plasma.

3. *Effect of edema on the plasma protein concentration.* The lack of a sustained diuresis following treatment was apparently also a factor favoring dilution rather than concentration of the plasma proteins. The three patients whose plasma protein concentration approached normal were completely free of edema at the end of treatment (Figure 6). In general, the patients with the least edema showed larger increases in plasma protein concentration. When edema was massive, the changes in plasma protein concentration were smaller and less consistent in direction.

Diuresis can occur without an increase in plasma protein concentration, and with an increase in al-

FIG. 4. EFFECTS OF TREATMENT WITH ALBUMIN ON THE PLASMA PROTEINS IN CASE 7

All data are plotted as per cent of normal.

The patient's total circulating protein was increased to normal levels after two days of treatment. Diuresis began on the first day and was complete by the end of the third day of treatment. On the third day, the plasma protein and albumin concentrations rose to the lower limits of normal.

FIG. 5. EFFECTS OF TREATMENT WITH ALBUMIN ON THE PLASMA PROTEINS IN CASE 1

All data are plotted as per cent of normal.

The total circulating protein (solid circles, broken line) is the product of the plasma volume, and the plasma protein concentration (open circles, solid line). During treatment, the total circulating protein was increased almost to the normal range (equivalent to 6% protein and a normal plasma volume), but was so diluted by extracellular fluid that there was no appreciable increase in plasma protein concentration. The colloid osmotic pressure and albumin concentration of the plasma were approximately doubled, but the patient was still massively edematous at the end of treatment.

bumin concentration no larger than that observed in cases with persistent edema (Figures 6 and 7). In no instance, however, did the plasma protein or albumin concentration approach normal levels without a preceding complete relief of edema (Figure 6, Table I).

4. *Total circulating protein.* When the total circulating protein is calculated from the protein concentration and volume of the plasma, it is evident that the injection of concentrated albumin can effectively replace the deficit of circulating albumin. The total circulating protein was approximately doubled, reaching 75-125% of the normal

* Follow-up period less than two weeks.

† "Standard" albumin contained sodium, approximately 400 m.eq. per liter. "Salt-poor" albumin contained sodium, approximately 80 m.eq. per liter.

‡ Dosage calculated in total grams/kg. edema-free body weight.

§ Concentrations of plasma protein, albumin and nonprotein nitrogen describe blood drawn under basal conditions on the morning after treatment. The level of albumin in blood drawn at the end of an injection may be as much as 50% higher than the figure given in this table (see Figure 2).

|| Albumin concentrations in italics are calculated from electrophoretic analyses, which yield results averaging 0.7 gram/100 cc. lower than the albumin concentration determined by the salting-out procedure used in the other measurements.

¶ Hematocrits at beginning and end of treatment are drawn under basal conditions, but minimum hematocrit invariably follows an injection of albumin.

** Edema is graded from 0 to 4 plus. Edema just detectable is graded 1 plus, definite and more extensive 2 plus, heavy and generalized 3 plus, massive 4 plus.

FIG. 6. RELATION BETWEEN CHANGES IN EDEMA AND IN PLASMA PROTEIN CONCENTRATION OF PATIENTS TREATED WITH ALBUMIN

Edema is expressed as per cent of usual body weight. Each arrow indicates the change in plasma protein concentration and in edema during a course of treatment with albumin, the head of the arrow representing conditions at the end of treatment. Note that patients with heavy edema generally had small increases or decreases in the plasma protein concentration after albumin treatment. A plasma protein concentration approaching normal was seen only when edema was eliminated.

total³ after two or three days of treatment (Figures 4 and 5). The proportion of albumin was usually increased until it equaled or exceeded the amount of globulin (Figure 2). This almost complete replacement of the plasma proteins was not regularly followed by a corresponding increase in plasma protein concentration because of the great dilution of the plasma.

5. *Duration of effects of treatment.* The effects of intravenous albumin on the circulating proteins persisted for only a short time after treatment was stopped. The plasma volume and albumin concentration declined as albumin was lost in the urine, usually reaching the control level within a week or two, depending on the rate of urinary loss. In chronic, stationary cases of nephrosis, the proportion of the blood proteins was often constant for months. When such patients were treated with albumin, the electrophoretic pattern returned with great accuracy to the pre-treatment picture. Persistent changes in the plasma proteins after treatment probably result from a more fundamental alteration in the pathological state.

³ "Normal circulating protein" = (plasma volume expected from height, edema-free weight, and sex) \times (7.5 grams of protein per 100 cc.).

In five such cases followed from four months to 2½ years, the proportion of albumin in the electrophoretic pattern varied less than 5% between any two analyses on the same patient. All five analyses of the serum of one patient and the two analyses of serum of another patient showed a proportion of albumin within $\pm 1\%$ of the mean. The proportion of albumin, reproducible within the error of the method, was grossly increased during treatment with albumin, but returned within four to 30 days (average 14 days) to the pre-treatment level.

FIG. 7. THE RELATION BETWEEN PROTEINURIA AND CHANGES IN PLASMA ALBUMIN AND TOTAL PROTEIN CONCENTRATIONS

Each point represents a course of albumin treatment, and indicates the change in concentration of plasma albumin or protein during treatment, compared with the amount of protein lost in the urine on the later days of treatment when proteinuria was maximal. Essentially the same relationship is noted when the per cent of total injected protein lost in the urine during treatment is charted in place of maximal proteinuria. The degree of edema at the end of treatment is indicated by the symbols as heavy (X), slight (open circle), or absent (solid circle). Note the relatively small effect of the large variation of proteinuria on the change in plasma protein concentration. Relief of edema was infrequent in patients who developed massive proteinuria, and was quite variable in patients with little proteinuria. The largest increases of plasma albumin and protein concentration occurred in patients who eliminated their edema while they retained protein.

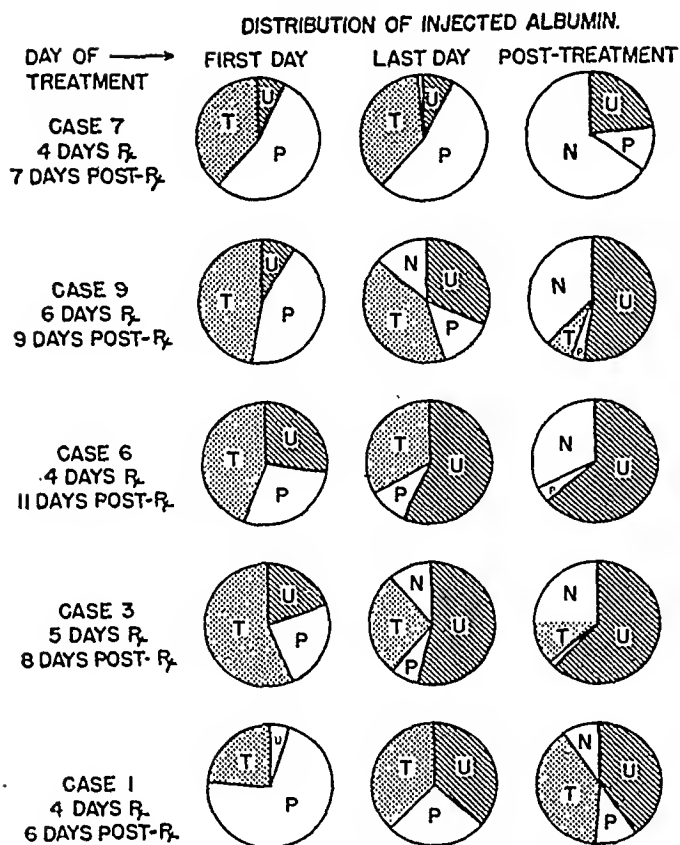

FIG. 8. FATE OF INJECTED ALBUMIN AFTER ONE DAY OF TREATMENT, AT THE END OF SEVERAL DAYS OF TREATMENT, AND SIX TO 11 DAYS AFTER THE END OF TREATMENT

P = Albumin retained in plasma in excess of control
 U = Albumin in urine in excess of control
 T = Administered albumin not found in plasma or urine
 N = Non-protein nitrogen from catabolism of albumin

The area of each circle represents the total dose of albumin administered, up to and including stated day. The distribution of the albumin is indicated by the areas of the various sectors.

Cases are arranged in order of response to therapy, from complete diuresis and normal protein level at the top of the chart (Cases 7 and 9) to failure to affect hypoproteinemia and edema (Cases 1 and 3) at the bottom of the chart. Note the relatively constant proportion of albumin stored in the tissues at the end of treatment. There is some correlation between amounts of albumin held in the plasma or lost in the urine, compared with the results of treatment in the first four cases. The failure of treatment in Case 1, however, can not be explained on this basis.

6. *Fate of injected albumin.* Much of the albumin given by vein disappeared from the circulation. A small part of the lost albumin appeared in the urine on the first day of treatment (Figure 8). If treatment was continued, a larger proportion was lost in the urine, reaching a plateau on the third or fourth day (Figure 9). In more

severe cases, the entire daily dose of albumin was lost in the urine after the first few days of treatment, but in milder cases, most of the administered albumin was retained in the body (Table I).

Between 33% and 55% of the injected albumin could not be found in the plasma or in the urine at the end of treatment (Figure 8). This protein must have passed into the extracellular fluid, and a part may have entered the cells, where it could be stored or burned. A few efforts were made to locate the lost protein. Samples of effusions and fluid before and after treatment were obtained when edema was not relieved by treatment. Analysis of these fluids for protein indicated that the injection of albumin increased the protein content of effusions and of interstitial fluid, but that both initial and final concentrations were very low. In Case 12, edema fluid, collected from each leg by Southey's tubes, contained 0.055% and 0.049% protein before albumin was given. The administration of 25 grams of albumin increased the concentration to 0.064% and 0.056% in the two legs. The protein concentration fell to the control level within four hours in the right leg, from which fluid continued to drain at a rate above 1 liter per day. The flow of fluid from the left leg fell to less than half the control rate for 48 hours, while the protein concentration remained at a level of 0.063%, and then the flow increased again, with a corresponding fall in protein concentration to the control level. This sort of data suggests that in the tissues, as well as in the plasma, shifts of fluid may affect the concentration of protein. One may recall a similar effect in Drinker's studies on the protein content of lymph. The important point is that the injection of albumin appeared to make only an infinitesimal change in a minute concentration.

The effect on the protein concentration of ascitic fluid was also very small. In Case 8, 150 grams of albumin in three days raised the protein concentration of 4 liters of ascitic fluid from 0.1% to 0.3%, while the weight dropped 1 kg., the plasma protein concentration fell slightly, and the plasma albumin concentration rose by approximately 65% above its initial level. In Case 12, 250 grams of albumin in five days raised the protein concentration of ascitic fluid from 0.1% to 0.2%. Although edema increased steadily despite treatment in this patient (see Table I), only 1 liter of ascitic

fluid could be obtained at the end of treatment; doubtless, more was present, but not a great collection.

Rough calculation from these data indicates that the amount of protein lost into the extracellular fluid would hardly account for all of the lost protein. This conclusion might also be inferred from the similar loss of albumin into the tissues, whether the patient is massively edematous or virtually edema-free (Figure 8). It seems likely that some of the protein was stored intracellularly. Some attempts were made to study such storage by the method of comparing nitrogen, potassium, and phosphorus balances, used by Albright, Reifenstein, and Forbes (12). The results were confused by the major changes in excretion of these elements, due to alterations in renal function and diuresis which followed albumin therapy. These changes will be commented upon in connection with nitrogen balance. At the end of two weeks,

most of the injected albumin nitrogen could usually be accounted for as excess albumin and non-protein nitrogen in the urine (Figure 8).

7. Effect on nitrogen balance. Study of the total nitrogen balance fails to describe adequately the changes during albumin therapy of nephrosis. It is important to separate the protein and non-protein fractions, which show different and sometimes opposite changes. It is also necessary to take into account changes in the volume and composition of body fluids which follow the administration of albumin (Figure 10).

Most of the albumin administered on the first day of treatment is retained in the body, but it has already been shown that more and more of the injected albumin may be lost on later days of treatment (Figures 8 and 9). When treatment is stopped, protein is lost in the urine in amounts considerably above the control level for several days. The excess protein in the urine is almost

FIG. 9. EFFECTS OF ALBUMIN ADMINISTRATION ON THE EXCRETION OF NON-PROTEIN NITROGEN, ALBUMIN, AND GLOBULIN IN THE URINE

The outer lines show the range, and the central line indicates the average for nine patients.

Note the immediate increase in urinary non-protein nitrogen on the first day of treatment, and the fall below the base-line after the end of treatment. The increased protein in the urine, rising to a plateau after several days of treatment, is composed almost entirely of albumin. The increased nitrogen excretion during the second week is probably related to the catabolism of albumin stored during treatment.

FIG. 10. EFFECTS OF ALBUMIN THERAPY ON NITROGEN BALANCE

In both balance charts, intake is plotted down from the base line (0) to the bottom of the shaded area. The nitrogen excreted by several routes is indicated as fecal, protein nitrogen (PN), and non-protein nitrogen (NPN). If the sum of these excretions falls below the base-line, the patient is in positive balance, i.e., intake exceeds output. If the total rises above the base line, the patient is in negative balance.

The upper chart represents total nitrogen balance, which reflects not only the metabolism of protein, but also changes in the volume and composition of the body fluids. In the second chart, the total balance is corrected for changes in body water, non-protein nitrogen concentration, and total circulating albumin, which are plotted below on an equivalent scale in terms of the grams of nitrogen which they represent. In this correction, non-protein nitrogen which is removed from the body fluids by diuresis and improved renal function is subtracted from the nitrogen excretion, since it does not represent any change in protein catabolism, but simply a shift from body fluids to urine. The nitrogen which accumulates in the body fluids after treatment is added to the nitrogen excretion, where it would appear if renal function were more efficient. Similarly, albumin which accumulates in the plasma during treatment, only to be excreted in the urine after treatment, is calculated as if it had not been retained. In the corrected chart, the storage and delayed catabolism of albumin in the cells can be seen, free from the extracellular and renal changes which complicate the total balance chart.

entirely albumin, as globulin excretion is little affected.

The changes in excretion of non-protein nitrogen (NPN) are different in several respects (Figures 9 and 10). At the beginning of albumin therapy, there is an increased excretion of NPN. The NPN concentration of the blood usually falls, averaging 7 mg. per 100 cc. lower at the end of treatment, with the largest decreases from blood levels above 30 mg. per 100 cc. After the end of treatment, the excretion of NPN falls temporarily below the control level, and the NPN concentration of the blood increases.

The initial rise of non-protein nitrogen in the urine can usually be related to the excretion of body water and to a fall in the NPN concentration of the body fluids and does not represent an increased catabolism of protein⁴ (Figure 10). The exact reverse of this effect may occur when treatment is stopped. Within two weeks after albumin therapy, an excess of nitrogen equivalent to the injected albumin is usually excreted or can be accounted for in the increasing volume and NPN concentration of the body fluids. These changes give an irregular appearance to the level of NPN excretion (Figures 9 and 10) which can be resolved into three phases: (a) increased renal excretion, (b) decreased renal excretion, (c) increase due to albumin catabolism. If the crude nitrogen balance is corrected so as to eliminate changes in volume and concentration of NPN and albumin in the body fluids, it is possible to visualize the storage and delayed catabolism of the albumin administered. Figure 10 shows the relative magnitude of these changes in a patient with good renal function and a moderate diuresis.

8. *Effects of loss of albumin in the urine.* The loss of albumin in the urine during treatment varied considerably from patient to patient. In some cases, the greatest daily loss was less than 20% of the injected albumin, but in other cases, most or all of the albumin was wasted in the urine. One might assume that this variability in loss would be reflected in the increase of plasma protein and albumin concentration during treatment. It is evident from the data in Figure 7 that variations in

⁴ This artificial change in external nitrogen balance appears to be caused by the increased glomerular filtration rate and diuresis which usually occur on the first days of albumin therapy (2, 18).

proteinuria have little systematic effect on the increase in plasma protein concentration, and only a slightly more dependable effect on the increase in albumin concentration during albumin replacement. This poor correlation probably is simply another indication that dilution of the added protein suppresses any large increase in concentration unless diuresis occurs. When proteinuria is relatively small and when diuresis occurs during treatment, a much larger increase in albumin and/or plasma protein concentration may follow (Figure 7).

The difference between the curves of total circulating protein in Figures 4 and 5 is probably the best indication of the effect of variation in proteinuria. In Figure 5, increasingly heavy proteinuria blocked further increase in total circulating protein after two days of treatment. In Figure 4, minimal loss from the plasma allowed cumulative increases in the total circulating protein on each day of treatment. Heavy proteinuria can thus greatly reduce the efficiency of albumin replacement and presumably may reduce the probability of a diuresis (Figure 7).

DISCUSSION

Concentrated human serum albumin has proved to be a useful therapeutic agent in five of our 13 cases of the nephrotic syndrome treated for brief periods. The relief of edema, with or without elevation of the plasma protein concentration, was followed by a considerable physical and psychological improvement. The effects of albumin on the blood proteins were temporary, but the reaccumulation of edema could be prevented or delayed by restriction of sodium intake. No fundamental change in the course of the disease has been apparent after albumin therapy. In these and many other respects, our results confirm the studies of Janeway (4, 5) and Thorn (6).

Some of the experimental observations during treatment with albumin support certain current views of the pathologic physiology of the nephrotic syndrome. For example, the effect of increased colloid osmotic activity of the plasma on fluid exchange at the capillaries was clearly demonstrated by the increased plasma volume after an injection of concentrated albumin.

Heavy loss of protein in the urine was obviously a serious drain on the patient's circulating pro-

tein. The loss of protein in the urine might not appear serious in the control periods, but when albumin was given intravenously, the increased plasma albumin concentration was reflected in an increased proteinuria. In general, heavy proteinuria during treatment occurred in patients who showed a very low plasma albumin concentration and/or a heavy proteinuria before treatment, indicating a high degree of renal permeability to albumin. In such patients, the loss of over half of the injected albumin in the urine greatly reduced the efficiency of plasma albumin replacement. In other patients with little albumin in the urine and a higher plasma albumin concentration before treatment, effective replacement of plasma albumin could be achieved quite economically (Table I).

The large variation from patient to patient in urinary loss of protein seemed to have a surprisingly small effect on the effects of treatment. Patients with massive proteinuria showed increases in plasma protein concentration nearly as large as those shown by patients who lost only a small amount of the injected protein in the urine. The other routes of loss from the plasma ("tissues") absorbed a fairly constant proportion of the injected protein. The variable fraction of albumin remaining in the plasma was apparently diluted to approximately the same concentration in nearly all cases. When diuresis occurred, however, *concentration* of the added protein could be achieved, and it was in this group of patients who lost their edema that the highest plasma protein concentrations were reached. These patients generally retained much of the injected albumin, but some other patients failed to eliminate their edema even though they retained equally as much of the injected albumin.

These findings do not support the concept that the edema of nephrosis is the simple consequence of a deficiency in albumin. It is necessary to distinguish clearly between replacement of the albumin deficit in grams of protein, and increasing the plasma protein concentration in grams per 100 cc. The albumin deficit can usually be made up by intravenous administration of albumin. To increase the concentration of plasma albumin and protein to normal is a much more difficult matter if diuresis does not occur.

In the presence of an excess of extracellular fluid, it seems difficult to raise the plasma protein concentration, since fluid dilutes the added albumin to a concentration approximating that of the original plasma. The administration of albumin thus increases the volume rather than the protein concentration of plasma. There are two obvious methods of increasing the plasma protein concentration under these circumstances. One solution is to remove the excess of extracellular fluid so as to permit the increase in osmotic pressure without excessive dilution of the blood, but this is not a simple matter if the kidneys fail to excrete the fluid. The other possible way to increase protein concentration is an apparent absurdity, the substitution of an osmotically inactive protein. Albumin may be osmotically ineffectual if its concentration increases equally in the plasma and in the interstitial fluid. This situation occurs in the ascites of some patients with hepatic cirrhosis (7, 13, 14) and in the edema fluid of patients with an unusual form of idiopathic hypoproteinemia (7). What little evidence we have indicates that the protein concentration of the edema fluid in nephrosis is too low to influence appreciably the effective colloid osmotic pressure of the plasma proteins. The logical conclusion of this line of thought is that injected albumin can be concentrated in the plasma of an edematous patient with nephrosis only if an effective diuresis ensues. If a diuresis does not follow, an anomalous situation occurs, in which the total circulating protein approaches normal, but the protein concentration remains very low, while the plasma volume becomes abnormally large. This mobilization of fluid at the peripheral capillaries without a corresponding diuresis throws the responsibility for the intractable edema directly on the kidney's failure to eliminate the excess of fluid.

The conjunction of plasma albumin depletion and of the retention of fluid is sufficiently common in nephrosis to justify the usual explanation of edema on the basis of hypoproteinemia. The observant clinician, however, will note that major changes in edema may occur without comparable changes in plasma protein or albumin concentration (15-17). We now have evidence suggesting that such changes in edema are due to variations in renal excretion of sodium and water, which are not explicable as a sequence of proteinuria, depletion of plasma albumin, lowered plasma colloid

osmotic pressure, and escape of fluid from the capillaries (18, 19). Change in the volume of the plasma and interstitial fluids must be considered as an independent factor which is equally as important as change in total circulating protein in determining the plasma protein concentration.

The importance of sodium retention in the production of edema is emphasized by the greater diuretic effect of salt-poor albumin (5, 6), suggested by the data in Table I. The sodium balance of these patients will be the subject of another report. It may suffice to say here that many patients with nephrosis have great difficulty in excreting sodium in certain phases of their disease and that treatment with albumin may or may not have a large effect on the excretion of sodium. In an occasional patient, sodium restriction seems to be unimportant (see Case 2, Table I) during a brief course of treatment with albumin or during a spontaneous relief of edema. In most patients, however, it appears to be necessary to limit the intake of sodium if albumin is to be used most effectively as a diuretic.

The questions of optimal dosage and duration of treatment with albumin were not examined in this study. Two relevant pieces of information may be noted, however. The very large increase in plasma volume, the increased venous pressure, and the dyspnea occurring in patients with vital capacity already reduced by effusions, all suggest that doses larger than 50-75 grams per day should be given with the greatest caution and abandoned at the first signs of cardiac or respiratory difficulty. The loss of efficiency of albumin replacement after the first two to four days of treatment suggests that if some improvement fails to occur within a few days, treatment with albumin is likely to prove a very slow, costly and inefficient diuretic. It would seem easier and safer to remove the fluid with Southey's tubes if intensive or prolonged treatment with albumin appears likely to be risky or inefficient. The most important function of albumin is to replace the deficit of plasma proteins. If this replacement does not result in diuresis, more efficient methods of disposing of the edema may be indicated.

SUMMARY

1. The administration of concentrated human serum albumin in dosage of 50 grams per day for

three to six days to patients with the nephrotic syndrome regularly results in a large increase of plasma volume and of total circulating protein.

2. The proportion of albumin in the plasma is considerably increased.

3. The plasma protein concentration is often not significantly increased, even though the total circulating protein is replaced to nearly normal levels, because of the great dilution of the blood by fluid mobilized from the tissues and not excreted in the urine. This result was observed in six of the 13 patients.

4. Five patients were essentially free of edema after four to six days' treatment. These patients showed a larger average increase in concentration of plasma protein and albumin than patients with persistent edema showed, but there was a large individual variation.

5. We have not observed a plasma protein or albumin concentration approaching normal levels without a preceding complete diuresis. Elimination of the bulk of the protein-free edema fluid is apparently necessary before the serum protein concentration can be raised to normal levels.

6. Diuresis can occur without an increase in plasma protein or albumin concentration greater than that observed with persistent edema. Small increases in the colloid osmotic pressure evidently suffice to mobilize a large amount of edema, *provided that the kidneys excrete the mobilized fluid.*

7. The replacement of plasma albumin is hindered to a variable extent by the loss of albumin in the urine, which increases as the plasma albumin concentration is increased by successive days of treatment. When proteinuria is massive, the efficiency of protein replacement becomes very poor after the second or third day of treatment. We were unable to increase the plasma protein concentration to a useful degree in any case with massive proteinuria. When proteinuria is slight, cumulative increase in total circulating proteins can be maintained for a longer period, and the likelihood of diuresis appears greater.

8. The increase in plasma protein and albumin concentration after treatment with albumin is only slightly larger in patients with smaller amounts of proteinuria, since the protein retained in the plasma is diluted to nearly the same extent as the protein originally present. When edema is eliminated, the

concentration of proteins and albumin in the plasma may increase more strikingly.

9. At the end of treatment, a fairly constant proportion of the administered albumin cannot be found in the urine or plasma. Some of this albumin appears in effusions and edema fluid, when present, but another portion is probably stored in the cells of the body. At the end of two weeks, all of the nitrogen injected as albumin can be accounted for as excess albumin and non-protein nitrogen in the urine.

CONCLUSIONS

1. Concentrated human serum albumin is an effective therapeutic agent for the temporary replacement of the deficit of circulating albumin in the nephrotic syndrome.

2. The efficiency of replacement is obviously reduced in patients with massive proteinuria.

3. It seems very difficult to increase the plasma protein concentration in the presence of an excess of edema fluid of low protein content because of the great dilution of added protein.

4. It is suggested that removal of edema may be a necessary step in increasing the plasma protein concentration, as well as vice versa.

5. Both the edema and hypoproteinemia of the nephrotic syndrome are aggravated by the failure of the kidney to excrete excess fluid, and are therefore not necessarily corrected by replacement of plasma albumin deficit.

MUCOLYTIC ENZYME SYSTEMS. VIII. INHIBITION OF HYALURONIDASE BY HUMAN BLOOD SERUM DURING THE NORMAL MENSTRUAL CYCLE AND PREGNANCY¹

By ERICK Y. HAKANSON² AND DAVID GLICK

(From the Department of Physiological Chemistry, the Medical School,
University of Minnesota, Minneapolis)

(Received for publication January 19, 1949)

While evidence has been presented in preceding publications of this series that the hyaluronidase inhibiting property of blood serum is increased in infectious diseases of both bacterial and viral origin (1-4) and in cancer (5), changes that accompany certain normal physiological states have not been investigated.

It is well known that hyaluronidase plays an important role in fertilization by enabling the sperm to disperse the follicle cells surrounding the ovum (6-8), and that normal serum can inhibit this effect (9). Another aspect of particular interest in the light of the finding of Wattenberg and Glick (10) that certain of the steroid hormones inhibit the activity of hyaluronidase *in vitro*, would be alterations in the serum inhibitory level accompanying hormonal changes. Dorfman (11) has stated that men of reproductive age have a significantly lower range of hyaluronidase inhibitor levels than a comparable group of women.

Since hyaluronidase plays an important role in the invasion of the animal host by various toxic and infectious agents (12), the possibility that the serum inhibitor has a protective function should be kept in mind. Rosalyn *et al.*, (13) reported that pregnant rabbits were more resistant to vaccinia infection than the non-pregnant, and Aycock (14) claimed that castrated monkeys were less susceptible to poliomyelitis infection after the administration of estrogenic hormone. Sprunt, McDearman, and Raper (15-16) demonstrated that pseudopregnancy or the administration of estrogenic substances resulted in inhibition of the spreading of India ink in the rabbit skin.

From the foregoing it would appear that the serum inhibitor might have an effect on fertilization, and the female sex hormones might possibly

influence resistance to infection through their effect on the hyaluronidase inhibitor. In order to gain some information relative to these points, as well as to observe changes with respect to certain normal physiological states, the present investigation was concerned with the variations that occur in the level of the hyaluronidase inhibitor in the blood sera of women during the menstrual cycle and pregnancy.

EXPERIMENTAL

Materials and Methods. The details of the preparation of the materials, the viscosimetric assay method used, and the calculation of results followed the recently described modifications (10) of the original procedure and mode of expressing inhibition (1). The hyaluronidase was prepared from bovine testicle and the hyaluronic acid from human umbilical cord. Hyaluronidase inhibition was expressed as the per cent inhibition effected by 0.02 ml. of blood serum under the conditions employed. The per cent inhibition was defined as $\frac{100(R - R_0)}{R}$ where (R_0)

is the time required to reduce the viscosity of the reaction mixture to one-half its original value, and (R) is the time required to reduce the initial viscosity to one-half after incubation of the 0.5 ml. of enzyme solution with 0.02 ml. of serum and 1.48 ml. of water for 10 minutes at 37.5° C. Because the inhibitor loses activity rapidly on standing at room temperature, it is important that the collection of samples be as uniform as possible. The blood was collected in clean tubes, allowed to clot, centrifuged, and the serum removed and immediately frozen. To eliminate differences in various batches of enzyme and substrate, all serum samples were stored at -20° C. until the collections were complete for a given experiment. All of the samples were then assayed the same day using the same enzyme and substrate preparations.

RESULTS

For the menstrual study, 10 healthy, regularly menstruating, unmarried women ranging in age from 22-28 were chosen as subjects. Since other diseases can influence the inhibitor values, any subject who developed a "cold," "gastrointestinal" upset, or any other disability was dropped from the study. The results of experiments on eight

FIG. 1. PER CENT INHIBITION OF HYALURONIDASE BY HUMAN BLOOD SERUM DURING THE MENSTRUAL CYCLE

Horizontal lines indicate menstrual periods.

individuals who completed the study are shown in Figure 1. The highest values are found during or immediately after actual menstruation although the magnitude of the changes was subject to great individual variation.

In the pregnancy study the blood samples were

not collected from the same individual over the entire period of gestation. However, sera from groups of 10 women from each trimester of pregnancy were assayed and it was found that, although the inhibitor values increased somewhat during the latter period of gestation, the differ-

FIG. 2. PER CENT INHIBITION OF HYALURONIDASE BY HUMAN BLOOD SERUM DURING PRE- AND POST-PARTUM PERIODS, AND ACCOMPANYING ORAL TEMPERATURES

ences were not statistically significant. Since the more dramatic changes in the inhibitor level were found to take place just before and during delivery, studies on 16 uncomplicated pregnancies were carried out beginning about a week before the expected date of confinement and continuing for about 10 days post-partum. The data of six representative cases are shown in Figure 2. It is clear from the curves that there is a consistent and significant rise in the per cent inhibition, which reaches a peak in from two to five days post-partum and is almost back to the pre-partum level by the 10th day. The rise can be detected in some cases as early as two hours after delivery. The temperature curves, which contain the highest recorded temperature for each 12-hour period, show that this elevation is not consistently paralleled by a rise in body temperature.

DISCUSSION

Although no *abrupt* change in the level of the hyaluronidase inhibitor was observed during, or soon after, the expected times of ovulation, in some of the cases the lowest values did occur during the middle of the cycle. However, the significance of this change is in doubt since its magnitude was negligible in some of the women. Further doubt of a correlation between inhibitor levels and sex hormonal changes follows from a consideration of the fact that no appreciable inhibitor changes were observed during the course of pregnancy. The point deserving major emphasis is the unequivocal post-partum rise in the level of the serum inhibitor. The significance of this observation is not clear at present. There may be a common factor, such as tissue destruction, in the variations of inhibitor noted in this investigation and the increase reported for infection and cancer. This possibility is being pursued further.

SUMMARY

Studies were carried out on the inhibitory effect of blood sera from 10 normal women during various phases of the menstrual cycle, and from 16 women with uncomplicated pregnancies before, during, and after delivery.

It was found that the highest inhibitor levels tended to occur during menstruation, although the individual variation in this elevation was great. The data do not permit of a correlation with sex hormonal changes.

No significant change was found during pregnancy or labor. A marked post-partum rise was observed which reached its maximum from the second to fifth days after delivery.

By JOSEPH B. KIRSNER, A. LEONARD SHEFFNER, AND
WALTER LINCOLN PALMER

(From the Frank Billings Medical Clinic, Department of Medicine, University of Chicago)

(Received for publication October 13, 1949)

Current emphasis on the use of proteins in the treatment of various disorders of the alimentary tract has stimulated a comparative study of certain aspects of protein metabolism in normal persons and in patients with gastro-intestinal disease. In addition to the usual nitrogen balances, microbiological assays were made of eight amino acids in food, acid-hydrolyzed whole plasma, tungstic acid filtrates of plasma (free amino acids), acid-hydrolyzed tungstic acid filtrates of plasma (free plus combined amino acids), hydrolyzed urine, and in feces. The amino acids measured were methionine, lysine, arginine, histidine, leucine, isoleucine, valine and threonine. The present paper deals with individual amino acid levels in the food, plasma, and urine of two normal adult men fed isocaloric diets of differing protein content. The data indicate that the fasting levels of amino acids in plasma are relatively constant, and that the excretion of amino acids in the urine does not fluctuate significantly despite considerable variation in amino acid intake.

METHOD OF STUDY

A. Subjects

Two healthy young men were studied in the metabolism section of Billings Hospital. In addition to the standard laboratory procedures, normal results were obtained for the following: (a) urea clearance test of renal function (1); (b) oral glucose tolerance; (c) hepatic function (2-9); (d) carbon dioxide ([10] p. 283), pH ([10] p. 796) and chloride ([10] p. 835), calcium (11), and phosphorus (12) content of serum; (e) plasma proteins (13); and (f) gastric secretion (14) (0.1 mg. histamine diphosphate per 10 kg. body weight).

Subject 1, J. D.; initial weight was 70 kg., height 175 cm. The basal metabolic rate, measured by the Benedict-Roth apparatus and calculated according to the standards of Boothby and Berkson, was +4; the basal calories were estimated as 1880.

Subject 2, R. G. H.; initial weight was 84 kg., height 187 cm. The basal metabolic rate was 0; basal calories were estimated as 1990. The blood and plasma volumes were measured by the Gibson-Evans method (15) at frequent intervals in this subject; the values were relatively constant, averaging 6198 and 2720 cc., respectively.

B. Diet

Normal activity was permitted. Fluids were allowed *ad libitum*, but the fluid intake and urine output were measured daily. The only medication consisted of a liquid vitamin B preparation given daily. Though the quantity of protein was varied, the caloric intake was kept uniform by adjustment of the carbohydrate and fat content of the diet. The number of calories was determined on the basis of the basal metabolic rate of each subject, with additional allowances for his usual activity. In Subject 1, the intake of calories was 3200, the carbohydrate ranging in the various periods from 403 to 477 gms. and the fat from 110 to 154 gms. In Subject 2, the intake of calories was 3190, the carbohydrate ranging from 415 to 475 gms. and the fat from 103 to 131 gms. Two to 4.0 gms. of table salt were added to the food each day. Crystalline methionine was added in periods 9 and 10; in all other periods the quantity of individual amino acids was varied by changes either in the amount or type of protein. Following a transitional interval of three days, each regimen was studied for two consecutive six-day periods.

C. Preparation and Analysis of Food, Plasma and Urine

The food was prepared in the kitchen of the metabolism section by dietitians trained in the problems of metabolic research. The food was weighed on a torsion balance before cooking; salt was the only seasoning; meats were broiled. The quality and quantity of the food were kept uniform throughout each regimen.

For analysis, a 30 to 40 per cent aliquot of a one-day supply of food (excepting pure carbohydrate and fat) was homogenized with distilled water in a Waring blender. A second aliquot of the same diet was prepared and analyzed approximately one week later; the results of both measurements were averaged.

At the end of each six-day period, following a 10-hour overnight fast, 100 ml. of venous blood were drawn, transferred to a screw-capped bottle containing 15 to 30 mg. of heparin, and mixed thoroughly. The blood was centrifuged and the plasma removed immediately. One-

¹ This study was supported in part by grants from the Evaporated Milk Association and American Dairy Association.

ml. samples were taken for the measurement of total nitrogen and for the assay of amino acids in acid-hydrolyzed whole plasma. Forty-ml. samples were used for the preparation of tungstic acid filtrates, as described by Hier and Bergeim (16). Aliquots of the tungstic acid filtrates were hydrolyzed with hydrochloric acid and assayed for total non-precipitable amino acids.

The urine was voided directly into glass containers and stored under toluene at ice box temperature (3-5° C.). The total six-day collection was combined and aliquots were taken for various analyses. Urea was measured by the urease method (17), free ammonia by the procedure described in Peters and Van Slyke (10) and the pH of the urine by the glass electrode method.

The total nitrogen of the food, plasma and urine was determined by a semi-micro-Kjeldahl technique, utilizing the Pregl-Parnas-Wagner apparatus and the digestion mixture of Campbell and Hanna (13). Amino acid assays were carried out by the microbiological method, as described elsewhere (18, 19). Recovery of measured amounts of pure amino acids added to the urine before acid hydrolysis ranged from 90 to 110 per cent. The validity of the microbiological procedures used in these studies has been confirmed by Toennies and Gallant (20). Leucine, isoleucine, arginine, histidine, valine and threonine were measured with *Streptococcus fecalis*; methionine and lysine with *Leuconostoc mesenteroides* P-60 as the assay organism.

RESULTS

The body weights of both subjects did not change significantly throughout the study. The total plasma proteins and the albumin-globulin ratios remained normal. The data for amino acids are presented in Tables IA and B. A change in concentration was considered significant if it exceeded the standard deviation² by two or more times.

Individual Amino Acids in Whole Plasma

The fluctuations in the methionine content of whole plasma in both subjects paralleled the varying intakes of this amino acid in food. For the seven other amino acids, there was no direct correlation between the quantities ingested and the plasma levels. The addition of crystalline DL-methionine to a diet adequate in this amino acid

² Standard deviation derived from expression:

$$S.D.^2 = \frac{[M.D.]^2}{n-1}$$

S.D. = standard deviation; M.D. = mean deviation; *n* = number of values measured.

(See footnotes under Table I-A.)

was accompanied only by a slight rise in the total methionine content of plasma in both subjects.

Individual Free Amino Acids in Plasma

The free amino acid content of plasma fluctuated slightly but did not parallel the varying intakes. Free methionine and free lysine increased minimally in both individuals after the addition of crystalline methionine to the diet; the concentrations of the other six amino acids did not vary significantly.

Combined Non-Precipitable Amino Acids in Plasma

Seven of the eight amino acids were consistently present, to some extent, in a non-precipitable "bound" form, *i.e.*, not precipitated with tungstic acid, yet not available to the assay organisms for growth. Non-precipitable combined methionine was found only in minute quantities or was totally absent. The combined non-precipitable amino acids in plasma varied in a random manner in both subjects. The addition of crystalline methionine was accompanied by slight increases in the levels of methionine and lysine only.

Amino Acid Output in Urine

The output of amino acids in the urine, as determined microbiologically, was very small (Tables

IA and B). The pattern of relative rates of excretion for the various amino acids was not directly related to the amounts taken in the food. Thus, the outputs of leucine and arginine were similar, although the intake of arginine was much smaller. The excretion of threonine exceeded that of valine although its intake was less. Histidine was excreted proportionately in far greater quantities than the other amino acids, averaging for the two subjects approximately 13 per cent of the intake. There appeared to be no correlation between the quantities of amino acids in the urine and the volume of urine or the output of urea nitrogen.

The fluctuations in excretion of histidine and threonine apparently paralleled the varying intakes. However, the outputs of methionine (periods 1-8), lysine, arginine, leucine, isoleucine and valine remained relatively constant. The quantity of methionine in the urine increased when 1.0 gm. of crystalline DL-methionine was added daily to a diet containing adequate amounts of this amino acid; however, the increment approximated only 0.5 per cent of the added methionine in J. D. and 0.7 per cent in R. G. H. The excretion of the other amino acids did not change significantly during the periods of methionine supplementation.

Subject 1 remained in approximate nitrogen

balance, and Subject 2, in positive nitrogen balance throughout the study (Table II). Retention of nitrogen increased markedly during periods 5 and 6, when the intake of protein was increased. The excretion of urea nitrogen, as expected, paralleled the quantity of nitrogen ingested. The small changes in output of free ammonia nitrogen did not appear significant.

Effect of Low Intake of Amino Acids

The effect of a markedly reduced intake of amino acids was investigated in Subject 2 during two additional periods, not included in the tables. In (a) the source of protein was a solution of peptone treated with 3 per cent hydrogen peroxide; the quantity of methionine ingested during the six-day period was decreased to 2.3 gms. In (b) the peptone solution was treated with 30 per cent hydrogen peroxide, the total intake of methionine being further reduced to 0.90 gm. In both periods, 1.25 gms. each of DL-tryptophane, L-tryosine, and L-cystine were added daily to compensate for the destruction of these amino acids by the peroxide. No effort was made to maintain the other amino acids at their original levels. The reduction in the intake of methionine in period (b) to 7.4 per cent of the subject's previous average intake was not

accompanied by a significant reduction in the methionine content of hydrolyzed whole plasma; however, the levels of free methionine decreased markedly. Although the intakes of the remaining amino acids, with the exception of arginine, also were considerably lower than in any of the previous periods, the concentrations of these seven amino acids in whole plasma likewise did not change. However, free lysine, histidine, leucine, isoleucine, valine and threonine decreased significantly; the concentration of free arginine did not vary. The combined non-precipitable levels in plasma did not diminish during the administration of the peptone diet. Supplementation of this regimen with 1.0 gm. of DL-methionine daily was not accompanied by significant changes in the concentrations of the eight amino acids in hydrolyzed whole plasma, or in the free amino acid levels. Non-precipitable combined methionine, lysine, arginine, and threonine increased slightly. The six-day output of methionine in the urine decreased from 0.108 gm. in period (a) to 0.04 gm. in period (b); the latter value, however, was smaller by only 27 per cent than the values obtained during the ingestion of much larger amounts of methionine. Of particular interest, perhaps, was the increased excretion of lysine, leucine, isoleucine,

0.56 gm. N in periods 9 and 10 in form of added crystalline methionine.

All values are averages of data for two successive six-day periods.

valine and threonine, the intakes of which had been reduced markedly. The output of arginine also rose although the quantity ingested was unchanged. The excretion of histidine diminished by 24 per cent, whereas the intake had been lowered by 84 per cent. During the same period (*b*) the output of urea nitrogen increased and the nitrogen balance became distinctly negative.

COMMENT

Plasma

The microbiological values in whole plasma for the eight amino acids are, with the exception of leucine, within the range listed for serum proteins by Block and Bolling (21). The data for leucine reported by the latter investigators were obtained by the oxidative method of Fromegat which, according to Hier *et al.* (22), yields values higher than are obtained by microbiological assay. The fasting whole plasma level of methionine averaged approximately 0.64 mg. per cent as compared with 0.73 mg. per cent, noted by Kinsell and his associates (23). The present data for free amino acids in plasma agree with the findings of Hier and Bergeim (24) in a group of 33 normal persons, and with the results for valine and histidine reported by Ackermann *et al.* (25). The individual amino acid values for the two subjects of this study were similar.

The whole plasma levels of lysine, arginine, histidine, leucine, isoleucine, valine and threonine did not fluctuate significantly although varying amounts were ingested. However, the methionine content of whole plasma apparently paralleled the varying intakes of this amino acid. Non-precipitable methionine accounted for only a minute fraction of these changes. Assuming that the constituent amino acid composition of plasma proteins remains constant, it may be postulated that a portion of methionine in plasma is attached to the surface of plasma proteins, is precipitable with the proteins by tungstic acid, yet does not constitute an integral component of the protein molecule. The concept of serum protein complexes has been discussed by various investigators (26-29). However, more data obviously are necessary to determine the significance of the fluctuations observed with methionine and to establish the validity of this hypothesis.

The effect of increased ingestion of one amino acid upon the individual levels of other amino acids

in the blood has been studied only occasionally. Hier (30) found that higher concentrations of free leucine, isoleucine and methionine in the blood of dogs, produced by feeding large amounts of the respective amino acids, were accompanied by decreases in the levels of certain other amino acids. However, the elevation in methionine was associated with a rise in the concentration of lysine. In the present study also, the increase in methionine, produced by the addition of crystalline DL-methionine to the diet, was accompanied by slight rises in the levels of free and combined non-precipitable lysine. The averaged data do not indicate the magnitude of the increase which resulted during the second period of methionine supplementation; the significance of these changes, however, remains to be determined.

Urine

The microbiological values obtained for total methionine, lysine, arginine, histidine, leucine, isoleucine, valine and threonine in the urine are within the ranges reported by Dunn and his associates (31), Woodson *et al.* (32), and by Eckhardt and Davidson (33).

Amino acid excretion was extremely small and relatively constant in relation to the amounts ingested. Eckhardt and Davidson similarly found no significant change in the quantity of amino acids excreted by a normal subject given varying amounts of protein. Although the output of methionine increased when the diet was supplemented daily by 1.0 gm. of the crystalline DL form, the increment for both subjects averaged only 0.6 per cent of the added methionine. Harper, Kinsell and Barton (34) noted a low output of methionine following its intravenous administration. Similar observations have been made by other investigators with respect to amino acid nitrogen (35).

It is to be noted that the number of calories was maintained at a constant level by adjustment of the carbohydrate and fat content of the diet. The data of Woodson *et al.* (32) have been interpreted as indicating that the caloric intake does not influence significantly the excretion of amino acids. However, this point has not been established conclusively, in our opinion. Until additional evidence is obtained, it would appear desirable, in studies of amino acid excretion, to control the caloric content of the diet. Preliminary experiments in our

laboratory suggest that the caloric intake may play a role in the urinary excretion of amino acids.

A small percentage of the amino acids in urine, as measured in this study, may have been derived from protein-like materials; Hanke (36) has reported the presence of a crystalline albumose in normal human urine which was excreted at a rate of approximately 50 mg. per day. Analysis of the amino acid composition of a sample of this material indicates, however, that less than 20 per cent of the total amino acids in urine may have been present in this form.

The increased excretion of amino acids in the urine of Subject 2 during the administration of an oxidized solution of peptone is of considerable interest. The oxidation obviously not only reduced the amino acid content, but also apparently disturbed the proper proportions of amino acids; the possible development of a toxic factor cannot be excluded. In this connection, Sauerblich, Pearce and Baumann (37) noted a higher excretion of "free" amino acids in the urine of mice fed diets containing protein of low biological value than among mice given proteins of ordinary or high biological value.

Both subjects remained in approximate nitrogen balance even when fed a moderately low protein diet. Nevertheless, nitrogen retention rose markedly when the intake of protein was increased. This finding suggests, perhaps, that measurements of nitrogen balance alone, at least for short periods of time, may not reveal minimally inadequate intakes of protein.

SUMMARY AND CONCLUSIONS

1. The amino acids methionine, lysine, arginine, histidine, leucine, isoleucine, valine and threonine were measured microbiologically in the food, plasma and urine of two normal adult men fed a variety of diets. In plasma, analyses were performed on acid-hydrolyzed whole plasma, tungstic acid filtrates (free amino acids), and on acid-hydrolyzed tungstic acid filtrates (free plus combined non-precipitable amino acids).

2. The fasting amino acid content of plasma, in general, did not fluctuate significantly despite considerable variation in the quantity of amino acids ingested in the food. Parallel fluctuations in the plasma levels and the amino acid intakes were observed in both subjects only for total methionine.

3. The output of amino acids in the urine was small, averaging 2.5 per cent of the intake. The pattern of relative rates of excretion for the various amino acids was not directly correlated with the respective individual amounts taken in the food.

4. Excretion of six of the eight amino acids was relatively constant despite considerable variations in intake. The outputs of histidine and threonine fluctuated slightly in relation to the varying intakes.

5. The addition of crystalline DL-methionine to a diet adequate in this amino acid was accompanied by increases in the whole plasma levels of methionine and of free and combined non-precipitable methionine and lysine. The urinary output of methionine increased slightly; no significant changes occurred in the excretion of the other amino acids.

6. In one subject the oral administration of a peptone solution treated with hydrogen peroxide and containing markedly reduced quantities of methionine, lysine, histidine, leucine, isoleucine, valine and threonine, was accompanied by definite decreases in the free levels of these amino acids. During the same periods, the amino acid outputs in the urine increased considerably.

ACKNOWLEDGMENTS

The authors express their appreciation to Dr. Martin E. Hanke for providing the sample of albumose; to Miss Blanche Parish, R.N., for supervision of the collections and care of the subjects; to Miss Minnie Brandt for preparation and administration of the diets, and to the subjects, Mr. John Doull and Mr. Richard Herz, for their cooperation.

FACTORS IN THE TREATMENT OF LAENNEC'S CIRRHOSIS. I. CLINICAL AND HISTOLOGICAL CHANGES OBSERVED DURING A CONTROL PERIOD OF BED-REST, ALCOHOL WITH- DRAWAL, AND A MINIMAL BASIC DIET^{1,2}

By GERALD KLATSKIN AND RAYMOND YESNER

(From the Department of Internal Medicine, Yale University School of Medicine, New Haven, Conn., and the Department of Pathology, Veterans Administration Hospital, Newington, Conn.)

(Received for publication February 25, 1949)

Fatty infiltration and cirrhosis of the liver can be produced experimentally in animals by defective diets, and can be prevented or cured by supplements of protein or lipotropes (1-10). Clinical observations suggest that dietary deficiency may also play a role in the pathogenesis of Laennec's cirrhosis in man (11), and a number of investigators have reported that dietary supplements of protein, vitamins and lipotropes affect the course of the disease favorably (11-18).

While it is generally agreed that these dietary supplements are of therapeutic value in human cirrhosis, it is still not known whether all are essential, whether their effects are due to a specific action on the liver, or to a more general one on the associated malnutrition, and whether the results of treatment are influenced by non-dietary factors. The difficulty in obtaining suitable controls, and the tendency to use multiple therapeutic measures simultaneously have delayed the solution of these problems.

The results of dietary therapy in cirrhosis are usually evaluated in one of two ways. In the first, longevity statistics are used as the criterion for comparing treated and untreated groups, the latter having usually been observed some years previously (11, 15, 16). In the other, the effects of various dietary measures are compared either in the same patient or in small groups, using serial clinical, functional and, in some instances, histological observations as the basis for comparison (13, 14, 17, 18). There are valid objections to both methods, but serial observations during alternating

courses of therapy in the same subject appear to offer the most practical means for conducting experiments under controlled conditions.

The natural history of Laennec's cirrhosis and its clinical and morphological manifestations are so variable that observations based on small groups are difficult to interpret, even when the rigid criteria of Volwiler (18) are met. Longevity statistics are even more difficult to analyze, especially when the controls have been observed some years before the experimental subjects. The difficulty in obtaining complete and reliable follow-up data in a large series, the relatively high mortality from unrelated diseases and the changing outlook in the treatment of the two most common serious complications, hemorrhage and infection, are some of the factors which distort the results. The importance of the experimental method and the type of control employed is well illustrated by the conflicting reports of Patek and Post (11) and Wade (19) on the effects of dietary therapy in cirrhosis, and of Volwiler (18) and Beams (14) on the effects of lipotropic substances.

Alcohol withdrawal and bed-rest are often factors in therapeutic experiments in cirrhosis, but are seldom taken into account in evaluating the results. The position of alcohol in the pathogenesis of Laennec's cirrhosis is still uncertain. Alcoholism is now generally regarded as an important factor conditioning malnutrition, but is not thought to have any more direct effect on the liver (11, 18). While there is no good evidence that alcohol acts directly as an hepatotoxin, several experiments suggest that it can play a role in the production of cirrhosis independent of its effects on food intake (20).

The importance of bed-rest has been stressed in infectious hepatitis (21), and may well be of

significance in the treatment of Laennec's cirrhosis (18).

During the past year we have been investigating the effects of dietary supplements of choline and protein in the treatment of Laennec's cirrhosis. As a preliminary each subject has been observed during a control period of three to seven weeks under conditions of complete bed-rest, alcohol withdrawal and a basic diet. Such striking changes have occurred during this period that the original experiments designed to test the efficacy of dietary supplements have had to be revised and then delayed. The following is a report on the clinical, functional and histological changes observed during the control period in 14 subjects.

MATERIAL AND METHODS

The 14 subjects chosen for investigation were routine admissions to the wards of the New Haven Hospital and the Newington Veterans Hospital. With one exception all had moderate to advanced Laennec's cirrhosis and

were admitted because of symptoms referable to it (Table I, Figure 1). Case 9v had a severe fatty infiltration of the liver without fibrosis and was admitted because of a small hemoptysis secondary to bronchiectasis. This patient was included in the series on the assumption that fatty infiltration of this type represents an early stage of Laennec's cirrhosis (22).

There was no selection of cases, all proved cases of Laennec's cirrhosis admitted to the wards of both hospitals being included in the study, provided they were able to stay in the hospital for a minimum of three weeks, were able to take food by mouth, and had not received intensive treatment before admission. All treatment prior to the beginning of the control period is indicated in Table II.

Each of the subjects had the liver function tests outlined below at one- or two-week intervals, and a liver biopsy by Vim-Silverman needle at the beginning and end of each experimental period. The two biopsy sites were never more than a centimeter apart. The site chosen depended on the size and position of the liver, and was epigastric in Cases 1, 2v, 3, 4, 6, 8v, 9v, 11v and 12, right subcostal in Cases 5v, 7v and 13v, and right intercostal in Cases 10 and 14.

Complications: a. = mild peripheral neuritis, mild ulcerative colitis; b. mild glossitis; c. asthma; d. bronchiectasis and small hemoptysis (cause of admission); e. peritonitis, RLQ abscess drained 2 mos. later, source not determined; f. mild glossitis and painful legs, no signs of neuritis; g. mild peripheral neuritis; h. marked cheilosis, glossitis, unilateral gynecomastia.

FIG. 1. CLINICAL STATUS OF SUBJECTS ON ADMISSION TO THE HOSPITAL

The length of the solid bars indicates the number of abnormal findings. The open bars indicate the total number of tests performed.

Esophageal varices demonstrated by X-ray.

Abnormal laboratory values: BSP retention $> 5\%$ in 45 minutes, $> 10\%$ in 30 minutes; serum bilirubin > 1.0 mg.%; alkaline phosphatase > 4.0 Bodansky or > 12 King-Armstrong units; cephalin-cholesterol flocculation $> 1+$; serum proteins < 6.5 gm.%; serum albumin < 3.0 gm.%; serum cholesterol < 150 or > 250 mg.%; prothrombin $< 70\%$; urine urobilinogen $> 1:10$; urine bile $1+$; thymol turbidity > 4.0 units.

The clinical studies and biopsies were performed by one of us (G. K.), while the other (R. Y.), who had no contact with the subjects nor any knowledge of their clinical status, reviewed all the sections of biopsy material at the end of the experiment, and evaluated them as outlined in Table III. Biopsy material was fixed in 10% formalin in absolute alcohol, cut at 5 microns and stained with Best's carmine and eosin and hematoxylin. Half the sections were also stained for reticulum and connective tissue with Laidlaw's stain.

The laboratory studies were carried out by identical methods in the two hospitals, with the exceptions noted, and included serum bilirubin (23), cephalin-cholesterol flocculation (24), thymol turbidity (25), bromsulphalein retention (26), serum alkaline phosphatase (27), prothrombin (28), urine bilirubin (29) and urine urobilinogen (30). Serum proteins were determined by the macro-Kjeldahl method at New Haven and the Phillips' falling drop method (31) at Newington. Serum cholesterol was

determined by the method of Peters and Man (32) at New Haven and by the Bloor method (33) at Newington. In a few instances the serum alkaline phosphatase was carried out by the King-Armstrong method (34) at New Haven; these values are marked "K" in the tables.

The experimental diet was started within a day or two of the patient's admission to the hospital, with the exceptions noted in Table II, and the patient was kept at bed-rest throughout the period of observation. The diet contained 1 gm. of protein per kilogram of body weight at the time of admission, allowance being made for accumulated fluid, 100 gm. of fat, and enough carbohydrate to raise the total intake to 30 calories per kilogram. Neither vitamins nor other dietary supplements were allowed, with the exception that patients with very low prothrombin levels were given vitamin K.

The control period (Period I) varied in duration from 21 to 49 days. Six of 14 subjects, who were available for further study under the same conditions, received

supplements of choline (Period II) and protein (Period III), in addition to the basic diet, following completion of the control period.

The present report is concerned primarily with observations made during Period I. The experiments dealing with the effects of dietary supplements are still in progress and will be discussed only briefly in connection with the interpretation of the effects of the control period.

RESULTS

Status on Admission. The clinical and laboratory findings are those usually seen in moderate to advanced Laennec's cirrhosis (Table I, Figure 1). The preponderance of males can be ascribed, in part at least, to the almost exclusively male population of the Veterans Hospital, where half the subjects were studied. Alcoholism and poor diet appeared to be important features in the past history, although reliable quantitative data could not be obtained. The high incidence of jaundice and ascites testifies to the severity of

the disease in most of the cases, and in only one (Case 9v) could the liver be regarded as being in a state of "compensation."

Hepatic enlargement was present in all but two subjects (Cases 10 and 14) and may have been related to the degree of fat infiltration noted histologically, although the causal relationship between the two is by no means certain (35).

The impairment of hepatic function demonstrated by laboratory methods was reasonably well correlated with the clinical status, the most significant findings being an elevation of the serum bilirubin level, increased bromsulphalein retention and a decrease in serum albumin. The serum cholesterol findings were of interest in that the total level was decreased in five, and increased in two. Of the six subjects in whom the cholesterol was fractionated, only two showed a pathological increase in the free:total ratio. The level of serum cholesterol and its fractions did not appear to be

related to the clinical, functional or histologic status of the liver, nor to its responsiveness to treatment.

The histologic findings were typical of Laennec's cirrhosis. Fatty infiltration of the parenchyma, fibrosis, periportal cellular infiltration and distortion of the architecture of the lobules predominated. Case 9v showed maximal fatty infiltration but no fibrosis, while Case 14 with the most marked fibrosis, showed little fat. No mitotic figures were seen, but the parenchymal cells frequently exhibited variations in size and staining qualities with many large binucleate cells and hyperchromatic nuclei, which were interpreted as probable signs of regeneration. Hyaline necrosis occurred much less frequently than in other studies of biopsy material in Laennec's cirrhosis, and may be related to our use of formalin-absolute alcohol fixative instead of Zenker's fluid (18). The individual histologic find-

ings were poorly correlated with specific tests of liver function, or with particular clinical manifestations, and their severity reflected only in a very general way the severity of the disease clinically. In Volwiler's experience there has been a similar poor correlation of histologic, functional and clinical findings (18).

Changes Observed at the end of the Control Period. Improvement in the clinical, functional and morphological status of the liver occurred in a significant number of the subjects (Tables II and III, Figure 2). The degree of improvement varied from case to case, and was not uniform by all criteria, but it appeared to be roughly correlated with the initial severity of the fat infiltration, an observation previously noted by others (18, 36). Thus, striking improvement occurred in Case 9v with the most marked fat infiltration (Figure 3),

FIG. 2. CHANGES NOTED DURING CONTROL PERIOD

The total length of the bars indicate the number of abnormal findings at the beginning of the control period, except in the case of weight and serum proteins where the original number of abnormal values is indicated by an arrow.

In the histological data \pm values were regarded as within normal limits. An increase in pleomorphism was regarded as a sign of regeneration and improvement.

FIG. 3. LIVER BIOPSY, CASE 9v

A. Before treatment, showing marked fat infiltration without significant fibrosis, distortion of the lobular architecture, and small compressed parenchymal cells (hematoxylin and eosin $\times 150$).

B. Forty-two days on control regime, showing almost complete loss of fat and restoration of normal lobular architecture and normal liver cords (Best's carmine $\times 150$). The liver had returned to normal size, and function tests were within normal limits at this time.

while the clinical course was rapidly and progressively downhill in Case 14 with minimal fat infiltration, even after the basic regime was replaced by a high protein, high caloric diet supplemented with choline and parenteral vitamins, liver extract and serum albumin.

The appearance of a complicating infection affected the course of the disease unfavorably in at least two subjects. Case 1 showed subjective and objective improvement during the first two weeks of the control period, but became more jaundiced, developed edema and exhibited an increase in ascites and a decrease in his serum proteins concomitant with the onset of a severe penicillin-resistant streptococcal sore throat in the third week. Unfortunately the control period was terminated at this point and choline was added to the basic regime. As the infection subsided there was clinical and functional improvement again. The cirrhosis was complicated by an unexplained suppurative peritonitis in Case 10, and there was little improvement during the control period except for a slight fall in the serum bilirubin level, and a decrease in fat infiltration histologically. Significant improvement did not occur until the infection was brought under control by surgical drainage of the abdomen combined with chemotherapy.

Subjective improvement in the initial symptoms

was observed in all the cases, except 10 and 14. This was accompanied by a decrease or loss of ascites, edema, jaundice, hepatomegaly and fever in more than a third of the group. Ascites subsided completely in five cases and decreased in one. The ascites was sufficiently severe in these to have required paracentesis in four.

Clinical improvement was usually accompanied by evidence of improved hepatic function, although there were several notable exceptions. Approximately half the subjects exhibited a fall in serum bilirubin and bromsulphalein retention and a rise in serum protein and albumin. In a significant number these values returned to normal. There was a fall in serum protein despite improvement by other criteria in two instances. In Case 4 the fall was due to a decrease in globulin without a significant change in the albumin fraction. In Case 10 both the total protein and albumin fraction fell despite morphologic improvement and a slight decrease in serum bilirubin. The fall in serum albumin in this instance may have been related to a loss by paracentesis and to an inadequate protein intake in the face of infection, rather than to a deterioration of hepatic function.

The changes in serum cholesterol were of interest. In every instance where the level was abnormal there was a rise or fall toward the nor-

mal range, depending on whether the initial value was low or high. The free: total cholesterol ratio was followed in only three subjects. Initially the ratio was abnormally high in two and normal in the third. It fell to normal in one, declined slightly in the second and did not change significantly in the third.

The changes in cephalin-cholesterol flocculation and thymol turbidity were not considered significant. The prothrombin level fell in five cases, but the fall was significant in only one instance (Case 5v). Only Case 2v showed a significant increase in prothrombin.

The most striking change observed histologically

FIG. 4. LIVER BIOPSY, CASE 2v

A. Before treatment, showing marked fibrosis, moderate fat infiltration, disruption of the normal lobular architecture, and bile duct proliferation (hematoxylin and eosin $\times 150$).

B. Twenty-eight days on control regime, showing a significant decrease in fat and larger, more normal appearing liver cords (hematoxylin and eosin $\times 150$). The liver had decreased in size, and function tests were within normal limits at this time.

FIG. 5. LIVER BIOPSY, CASE 14

A. Before treatment, showing very extensive fibrosis, marked disruption of the lobular architecture, bile duct proliferation, and slight fat infiltration (hematoxylin and eosin $\times 150$).

B. Thirty-two days on control regime, showing complete loss of fat despite obvious deterioration of clinical and functional status. The apparent shrinkage of the liver cords is due to the stain employed (Boett's carmalum $\times 150$).

was a decrease in fat infiltration which occurred in all but one subject (Figures 3-5). The fat actually disappeared in three instances, including Case 14 whose clinical and functional status deteriorated (Figure 5). Further evidence of healing was found in the increased regeneration of parenchymal cells, the decrease in periportal cellular infiltration and the improvement in intralobular organization, which occurred in almost half the cases. The other signs of histologic improvement noted in Table III occurred less frequently. There was no significant decrease in fibrosis in any of the cases.

The validity of the method of sampling the liver by needle biopsy is obviously open to some question, but the uniform trend of the changes observed suggests that they were of significance.

COMMENT

It is apparent from these observations that significant improvement may occur in Laennec's cirrhosis under conditions of bed-rest, alcohol withdrawal, and a minimal basic diet, and that these factors must be taken into consideration in evaluating the specific therapeutic actions of dietary supplements. The results, however, do not warrant any definite conclusions regarding the relative efficacy of the basic diet and diets supplemented with protein or lipotropes, nor do they indicate which of the factors in the control regime was responsible for the apparent improvement observed.

The six subjects who received supplements of choline in Period II and of protein in Period III, under continued conditions of bed-rest and alcohol restriction, showed progressive improvement clinically and histologically. Since there was no significant change in the rate of recovery, as compared to that in Period I, it could not be determined whether the observed effects were due to the specific action of these supplements, or to prolongation of the period of bed-rest and alcohol withdrawal. It may not be possible to evaluate the role of dietary supplements in the treatment of cirrhosis until the factors responsible for improvement during the control period are better understood, and until the maximum effects of the basic regime have been determined.

The methods of study employed by Volwiler and his associates (18) were sufficiently similar

to ours to permit some comparisons of the effects of their high protein, high caloric diet with those of the basic diet used in these experiments, under the same conditions of restricted activity in a hospital. There was no significant difference in the clinical improvement observed in the two groups, but the subjects on the better diet showed more complete removal of fat histologically, and greater and more consistent increases in serum albumin. These differences, however, may not have been due to the diet, since Volwiler's subjects were less severely ill than ours, judged both clinically by the incidence of ascites and jaundice, and histologically by the degree of fibrosis present. Only four of his 13 subjects had ascites, compared to 10 of the 14 on the basic diet, and only six showed more than one-plus fibrosis histologically, compared to 13 in our group. On both diets the only significant rises in serum protein occurred in the non-ascitic group, and in several instances the level fell when ascites was present. There was no clear-cut correlation, however, between the degree of fibrosis and the rate of fat removal from the liver. While the differences in the rate of fat removal in the two groups may have been related to differences in the severity and duration of the disease, the possibility that they were due to the diet cannot be excluded.

Franklin and his associates (17) have also studied cirrhotics by the serial biopsy technique, and have concluded that supplements of choline and methionine have specific therapeutic effects. Their results are difficult to interpret since they had no control group, and since their basic diet had a relatively high protein and caloric content and included large supplements of vitamins. Volwiler (18), under somewhat different conditions, on the other hand, has found that lipotropes do not augment the effects of a high protein diet. Franklin's comments are of interest in connection with the observations being reported: "Shorter periods of observation are desirable in view of possible spontaneous remissions which may occur with longer control periods. Even in the shorter periods used in this study, however, the possibility of spontaneous improvement may raise difficulties in evaluating the role of therapy."

Further work is needed to determine what factors were operative during our control period to account for the improvement which occurred.

The possibility cannot be excluded that the basic diet employed was an important factor. The optimal protein requirement for the normal adult is still a matter of speculation, and it is known to be influenced by a great many factors. The standard of 1 gm. per kilogram of body weight daily, however, is widely accepted, and it is generally agreed that larger amounts are required in overcoming malnutrition and in facilitating tissue repair. Accordingly, the requirement in cirrhosis is usually given as 1.75 to 2.0 gm. per kilogram, although it is recognized that these values have not been established under varying dietary conditions (18). By this standard the basic diet was suboptimal in regard to protein. While the caloric supply appeared to be inadequate for some of the subjects, there was no clear-cut evidence that there was a deficiency of protein. Eight of the subjects lost weight on the diet, but in only a few was there obvious tissue wasting, while in the others a decline in weight due to water loss could not be excluded. It is quite possible that under the experimental conditions of bed-rest, a moderate carbohydrate supply and a maintenance caloric intake, 1 gm. of protein per kilogram met both the general nutritional needs and the specific requirements of the liver. The somewhat slower removal of fat from the liver, compared to Volwiler's experience (18), and the fall in serum proteins in some of the subjects are the only indications that the protein intake may have been suboptimal in some instances.

The nutritional requirements of the liver are not known precisely, nor have the factors which influence them been studied in man. In animals, at least, there appears to be a relationship between the requirement of lipotropic substances and the over-all metabolic activity (37). Thus, deficient diets which retard growth (38), starvation (39) and the administration of thiouracil (40), lower the choline requirements of rats. There is suggestive evidence that a similar relationship may exist in man. Low protein diets known to produce fatty infiltration and cirrhosis of the liver in children are usually high in carbohydrate and caloric content (41). Low caloric, low protein diets, on the other hand, do not produce liver damage in man, under some circumstances at least (42). It is conceivable, then, that the decrease in liver fat observed in our experiments, and even the improvement in liver function, were starvation effects.

This might account for the apparent histologic improvement despite obvious clinical deterioration in Case 14, and for the changes observed in the subjects who lost weight during the experiment, but could hardly account for the improvement which occurred in those who gained weight.

If the choline requirement of the liver is related to the caloric intake, alcoholism may play a dual role in creating a choline deficiency—first, by raising the caloric intake without a concomitant increase in protein, and secondly, by reducing the food intake. The caloric value of alcohol is usually disregarded even in well-controlled, paired-feeding experiments (20), and may account for the apparent failure of a normal protein intake to protect the liver against fat infiltration. Moreover, a large enough supplement of choline or protein might prevent or reduce fat infiltration and mask the effects of alcohol, and might account for the failure of some observers (11, 18) to demonstrate any deleterious effects when alcohol is administered to cirrhotics on high-protein diets.

The importance of bed-rest in acute liver disease has been recognized for some time, and recently it has been stressed in the treatment of cirrhosis (18). It is not known whether rest exerts its favorable action by promoting healing, as it does in other inflammatory diseases, or whether it does so by altering the metabolic activities of the liver in some equally obscure way. The decrease in hepatic blood flow during exercise (43) may be of importance in this connection. The degree of physical activity may also be one of the factors which determine the lipotropic requirement of the liver, just as in the case of the rate of growth.

It should be emphasized that whatever the specific effects of the diet on the liver prove to be, the patient with Laennec's cirrhosis will still require a well-balanced diet to overcome the usually associated malnutrition. Future studies may reveal that dietary supplements have no specific effects on the liver, but rather improve the nutrition generally permitting the liver to heal under more favorable conditions.

SUMMARY AND CONCLUSIONS

1. Significant clinical, functional and histological improvement has been observed in patients with Laennec's cirrhosis under controlled condi-

tions of bed-rest, alcohol withdrawal and a minimal basic diet.

2. The effects of such a control period must be taken into account in evaluating the specific effects of dietary supplements on the liver.

3. The results do not warrant any conclusions regarding the relative importance of bed-rest, alcohol withdrawal and diet in producing the effects observed during the control period.

OXYGEN SATURATION OF STERNAL MARROW BLOOD IN POLYCYTHEMIA VERA¹

BY BERNARD M. SCHWARTZ AND DANIEL STATS

(From the Medical Services, Cardiovascular Research Group, and the Hematology Laboratory,
The Mount Sinai Hospital, New York City)

(Received for publication March 9, 1949)

The polycythemia observed at high altitudes and in certain forms of pulmonary and congenital heart disease has led to the acceptance of the view that anoxia is an erythropoietic stimulus. In polycythemia vera, however, the oxygen saturation of the arterial blood has been found to be normal. Observers have, therefore, sought in the bone marrow itself for evidence of anoxia in this disease. Reznikoff *et al.* (1) demonstrated changes in the capillaries and arterioles in the bone marrow of patients with polycythemia vera and postulated decreased blood flow with subsequent anoxia as the erythropoietic stimulus. Chemical evidence of such anoxia has as yet not been obtained.

It has likewise been maintained that marrow anoxia is the stimulus to red cell production in anemia, as for example, after hemorrhage. Recently, however, Grant and Root (2, 3) have determined the percentage saturation and oxygen tension of bone marrow blood in dogs made anemic by bleeding and found no significant difference from the control animals.

These considerations led us to a study of the oxygen content in bone marrow blood in various diseases in man, adapting the method of Grant and Root.

After the studies to be reported in this paper had been completed, the work of Berk, Burchenal, Wood, and Castle (4) on the same subject was published.

MATERIALS AND METHODS

Fifty-two sets of determinations in 50 patients are presented here. From each patient, within a period of several minutes, specimens of bone marrow blood and brachial arterial blood were obtained. In 35 instances antecubital venous blood was drawn without stasis. All bloods were chilled until the analyses were performed.

At the time of withdrawal of the blood specimens for analysis, the patients were recumbent in bed, having

rested quietly for at least ten minutes. Experiments were usually performed between 9 and 10 o'clock in the morning, about two hours after breakfast. More attention was not paid to the establishment of absolutely basal conditions because the act of sternal marrow puncture induced a degree of anxiety in most patients which was of far greater moment than the other factors affecting the basal state.

The sternal bone marrow aspiration was performed by the usual technique at the level of the second interspace with a number 17 bone marrow needle and stylet. After the marrow had been entered, the stylet was withdrawn. In only two patients, one with polycythemia vera and one with an hemangioma of the spleen (not included in the present series), was there a spontaneous welling up of blood into the hub of the needle. In the other patients, a preliminary gentle aspiration with a 10 cc. syringe was performed until blood just appeared in the syringe. The syringe was then discarded and the patients were instructed to perform a momentary Valsalva experiment when necessary, whereupon bone marrow blood was seen to rise into the hub. The tip of a Roughton-Scholander micro-pipette, containing dried heparin, was immediately inserted well below the level of the blood to the junction of the hub with the needle proper. The operator's finger was held over the opposite end in order to prevent blood in contact with air from entering the pipette. Forty cu. mm. were aspirated and transferred to a Roughton-Scholander analyzer for immediate determination of oxygen content. From 0.75 cc. to 1.0 cc. of bone marrow blood was then withdrawn with gentle suction into a 2 cc. syringe containing dried heparin for the determination of oxygen capacity.

Oxygen determinations were performed by the method of Roughton and Scholander (5). For the capacity measurement blood was saturated with oxygen by the aeration of 0.5 to 1.0 cc. for 15 minutes in the syringe in which the specimen had been collected. Correction for dissolved oxygen in both the saturated and unsaturated specimens was made using the figures of Sendroy *et al.* (6).

The patients were divided into four groups, namely, controls, patients with polycythemia vera, anemia and anoxic anoxia. The "control" group consisted of afebrile patients, some of whom were convalescent from a variety of diseases and who manifested no hematologic, cardiovascular, or pulmonary abnormalities. The polycythemia vera group consisted of all patients with this diagnosis, regardless of the stage of therapy. The anemics consisted of patients whose arterial oxygen capacity was less than

¹ Aided by a grant from the Linde Air Products Company.

15 volumes per cent, corresponding to a hemoglobin content of 11.0 grams per 100 cc. The anoxic group included patients whose arterial oxygen saturation was below normal. In addition to the anoxic anoxia which all patients in this group manifested, some were presumed to have stagnant anoxia on the basis of congestive heart failure.

In the collection of "bone marrow blood" for the determination of oxygen content and capacity several possible sources of error are to be considered:

1. As indicated previously a preliminary aspiration with a 10 cc. syringe and the performance of the Valsalva maneuver were usually necessary in order to obtain a free flow of bone marrow blood into the hub of the needle. Did these pressures induce changes in the oxygen content of the bone marrow blood obtained? For a brief period the level of bone marrow blood in the hub was exposed to air. Did this brief exposure also induce changes in the oxygen content of the specimen drawn? It is likely that whatever error was introduced affected the controls and the test groups similarly. It was believed that such changes took place only at the surface of the blood column and that errors from these sources could be eliminated by inserting the tip of the pipette well below the level of the blood. This opinion was substantiated by subjecting blood to similar treatment in a dummy experiment.

2. Another source of error is that "bone marrow blood" is not a relatively constant mixture like peripheral blood. When material is aspirated through a needle in the bone marrow, a variable proportion of marrow elements, stagnant red blood cells, and actively flowing blood is obtained. This is evident grossly in that some bone marrow specimens appear homogeneous whereas in others yellowish grey particles are seen. In addition, changes in circulation may have occurred at the tip of the needle in the marrow cavity. An indication of the magnitude of these errors can be obtained by comparing the oxygen capacities of bone marrow and peripheral blood in the same individual. The value, arterial blood oxygen capacity minus bone marrow blood oxygen capacity, had an extreme range from +2.3 to -1.1 volumes per cent. The mean difference, however, was +0.3 volumes per cent, just beyond the error of the method, showing that there was a slight dilution by bone marrow elements. Using the method of Grant (7), in a number of instances, we determined the oxygen capacity of bone marrow blood drawn before and after the removal of 1 cc. and found a similar variation. It should be pointed out in this connection that Grant and Root (2) found an average difference of +1.3 volumes per cent between venous and bone marrow oxygen capacity in dogs. As an indication of the degree of error brought about by variation in the oxygen capacity of bone marrow blood, we have calculated the percentage saturation of bone marrow blood on the basis of the capacity of both bone marrow and arterial blood. The mean and the standard deviation in the control and in the other groups were not changed significantly by either method of calculation. We have therefore used the figures for percentage saturation of bone marrow

blood calculated on the basis of bone marrow capacity in the presentation of our results.

RESULTS

The results in individual cases are shown in Tables I through IV. Table V compares the results in the four groups of cases. The oxygen contents are given in volumes per cent. Letter A refers to brachial arterial blood and letters BM to sternal bone marrow blood.

Percentage saturation of bone marrow blood with oxygen: It is evident that there was a wide variation in the percentage saturation of bone marrow blood with oxygen in all four groups, this being especially pronounced in the control group. The values for patients with anemia tended to fall in the lower range of the control values, but the difference between the means was not statistically significant. The values for the anoxic patients had a similar, but somewhat wider range, and the mean was somewhat lower. The difference between the means of the control and anoxic groups was on the border of significance (p was between

and bone marrow blood (A-BM difference) displayed a similar wide range of variation, greatest in the control and anoxic groups. The A-BM values for the anemics tended to fall in the lower range of normal, but the difference between the means was not significant. The patients with anoxia, due at least in part to the heterogeneous make-up of the group, showed no significant difference from the controls. The A-BM values for patients with polycythemia vera, however, were in general lower than the controls, although there was overlapping. The difference between the means in the latter two groups was statistically significant (p was between 0.01 and 0.001).²

The values for antecubital venous blood oxygen content displayed the wide range of variation previously reported by others. With few exceptions, the venous oxygen content was lower than the bone marrow content.

DISCUSSION

The wide range of variation in the oxygen content and percentage saturation of bone marrow blood found in this study confirms the results of Grant and Root (2, 3) in dogs and of Berk and co-workers (4) in man.

By the present methods, with their limitations as discussed above, it was not possible to demonstrate bone marrow anoxia in polycythemia vera. In this respect, our findings are in agreement with those of Berk *et al.* However, whereas they found no significant difference in the mean value of the percentage saturation of bone marrow blood in the controls and in polycythemia vera, our findings show a significantly higher value for the latter. In common with Grant and Root (2), we confined our analyses of bone marrow blood oxygen content to

the first several drops of blood appearing in the needle. Berk *et al.* withdrew 5 cc. by syringe in their "old" technique and 1 cc. in their "new" technique performing analyses upon this blood. It is significant that our average value for percentage saturation in the controls, 78.7 per cent, was essentially the same as that obtained by Grant and Root in control dogs. The corresponding value for normals found by Berk *et al.* was 88.6 per cent by their "new" method, which is not significantly different from their value for polycythemias, 87.3 per cent, nor from our value for polycythemia vera, 88.6 per cent. If difference in technique accounts for the varying findings, it is not clear in the comparison of these results why this difference affected only the normals, where we differed by 9.9 per cent, while identical figures were obtained in polycythemia vera. A possible explanation may be that in polycythemia vera the bone marrow is hyperplastic and extraordinarily vascular so that the first cubic centimeter of blood brought into the syringe may represent bone marrow blood. On the other hand, in normal patients, where the bone marrow is not hyperplastic nor unduly vascular, only a portion of this cubic centimeter may come directly from the marrow. The remainder may be drawn in from extra-marrow sources. In support of this explanation is the fact that in four controls, we have found the oxygen content of bone marrow blood drawn after the removal of 1 cc. to be higher than the oxygen content of blood obtained before such removal. This finding, however, is at variance with the results obtained by Grant and Root in dogs, where successive bone marrow specimens showed the same oxygen content.

The other difference in technique, namely, that Berk *et al.* secured a spontaneous flow of marrow blood by having their patients turn to one side whereas we induced flow by gentle suction, does not, in our opinion, account for the different results because of the dummy experiments performed by both sets of investigators, which showed no change as a result of such manipulations.

The percentage saturation of bone marrow blood in polycythemia vera would be higher than normal even if the arterial-bone marrow oxygen difference were the same in the two groups. Actually, the A-BM difference was lower in the polycythemic

group, thus accentuating the difference in percentage saturation. Ordinarily decreased arteriovenous oxygen difference implies increased blood flow, provided oxygen consumption is not decreased. Overall oxygen consumption in polycythemia vera is increased or normal. We are aware of no *in vivo* studies of oxygen consumption of bone marrow itself. One would expect an increased oxygen consumption in hyperplastic marrow. Therefore, increased blood flow compatible with an hyperplastic, highly vascular marrow may be present. This would impart to the circulation in the marrow in polycythemia vera a unique character since there is evidence that the general circulation in this disease is slowed. The theoretical possibility remains, however, that oxygen consumption of bone marrow in polycythemia vera is decreased (histotoxic type of anoxia or arteriovenous shunting). In this case the low A-BM difference would not necessarily indicate increased blood flow.

In agreement with the findings of Grant and Root in post-hemorrhagic anemia in dogs we have been unable to demonstrate a significant difference from the controls in the percentage saturation or arterial-bone marrow oxygen difference of a small number of cases of pernicious and hypochromic anemia. This may be due, in part, to the fact that our methods are not sensitive enough to detect small differences in the face of great normal variation.

In patients with anoxic anoxia the method was adequate to detect low percentage saturation values in the bone marrow blood. That they were not lower is due possibly to various compensatory factors, such as increased blood flow and increased oxygen capacity.

SUMMARY AND CONCLUSIONS

1. Oxygen content, capacity, and percentage saturation of bone marrow blood were determined in man in a group of controls and in patients with polycythemia vera, anemia, and anoxic anoxia. The limitations of the method are discussed.

2. The percentage saturation of bone marrow blood was greater and the arterial-bone marrow blood oxygen difference was smaller in patients with polycythemia vera than in controls. This finding does not support the theory that there is a local bone marrow anoxia due to decreased blood flow in polycythemia vera, but is compatible with either increased blood flow or decreased oxygen utilization by the marrow in this disease.

3. No significant differences were found between anemias and controls, in a small number of cases.

4. In patients with anoxic anoxia the percentage saturation of bone marrow blood with oxygen was lower than in the controls.

IV. RESPONSE OF CITRIC ACID LEVELS OF NORMAL ADULTS AND CHILDREN TO INTRAMUSCULAR INJECTION OF EPINEPHRINE¹

By JOSEPH B. PINCUS, SAMUEL NATELSON, AND JULIUS K. LUGOVOY

(From the Pediatric Research Laboratory and the Department of Biochemistry of the Jewish Hospital of Brooklyn)

(Received for publication December 22, 1948)

Our earlier observations that oral administration of glucose would cause a lowering of citric acid levels in humans (1, 2) led us to investigate the effect of epinephrine on citric acid levels.

One-half minim of a 0.1% solution of epinephrine in water per kilogram of body weight was administered with a maximum dose of ten minims to any individual, after a 12-hour fasting period. Thus all adults and most children studied received a dose of 10 minims intramuscularly. Serum glucose and citric acid levels were followed at short intervals as shown in the charts below. In view of the varying response of different individuals, average curves were not drawn but representative results are shown in Figure 1 for children, and Figure 2 for adults. Glucose determinations were carried out by the method of Folin and Wu (3) and citric acid determinations were carried out as described before (4). This latter method has been in routine use in our laboratory for more than a year and is in error by less than 5%.

Comparison of fasting serum levels of citric acid with the maximum level reached after epinephrine administration is tabulated in Table I. Results obtained on the serum of children and adults are averaged together since no significant difference was noted between the two groups.

TABLE I

Comparison of fasting serum levels of citric acid with citric acid levels obtained after epinephrine administration

No. cases	Average fasting level	Average maximum level	% increase over fasting level	P value fasting vs. max. level
28	mg. % 2.16	mg. % 2.85	32	5×10^{-3}

In order to compare these results with the effect of insulin, similar studies were carried out with insulin administered intramuscularly. This type of study had been reported before but no curves

were shown (1). Figure 3 shows four typical curves obtained in this study.

We have also studied the effect, on citric acid levels, of intravenous administration of glucose (5). Figure 4 shows a typical result obtained after the intravenous administration of glucose to a 100 lb. girl (50 mg./lb.). A total of 5 grams of glucose dissolved in 25 ml. of water was administered within a one-minute period. This curve is included for comparison with the curves obtained on intramuscular administration of epinephrine.

DISCUSSION

It can be seen readily from Figures 1 and 2, and Table I that intramuscular injection of epinephrine will cause a rise in citric acid serum levels. This is in contradistinction to the effect of insulin (Figure 3) or glucose, either orally (1, 2) or intravenously (Figure 4), all of which cause a lowering of citric acid levels.

Earlier (2) we reported that certain convulsives and diabetics responded to administration of glucose with a rise in citric acid levels rather than a fall. We are investigating the possibility that in these cases some abnormality exists which results in excessive epinephrine secretion during the test.

A preliminary drop in citric acid levels, from the fasting level, was observed in 17 out of the 28 cases. The average citric acid level for all cases, 15 minutes after the administration of epinephrine, was 3% lower than the fasting level. Statistical comparison of this level with the fasting level yielded a *P* value of 0.6 which is not statistically significant. Thus it can be said that no significant rise in citric acid levels occurs within the first 15 minutes. The rise in glucose levels during this time (within 15 minutes) is definitely significant, being 50% higher than the fasting level. Compar-

¹ Presented at the Meeting of the American Chemical Society at Washington, D. C., August 30, 1948.

RESPONSE OF CITRIC ACID AND GLUCOSE LEVELS
TO INTRAMUSCULAR ADMINISTRATION OF EPINEPHRINE (NORMAL CHILDREN)

FIG. 1. REPRESENTATIVE CURVES ILLUSTRATING THE EFFECT OF INTRAMUSCULAR INJECTION OF 0.5 MINIMS/KILO OF EPINEPHRINE ON SERUM CITRIC ACID AND GLUCOSE LEVELS (NORMAL CHILDREN)

ing this level with the fasting level a P value of 10^{-7} is obtained. Thus the response in changes of glucose levels on administration of epinephrine is more rapid than the response of citric acid levels. These observations would imply that the action of epinephrine, in its effect on citric acid levels, is probably more indirect than the mechanism whereby it acts in causing a rise in serum glucose levels.

Other acids like pyruvic and lactic acids which are intermediates in glucose metabolism increase when glucose, insulin or epinephrine is administered (6-12). However, the literature is not in

complete agreement as to the effects of insulin and glucose administration on serum lactic acid levels (13).

Citric acid is distinctive in showing a lowering of the serum levels on the administration of insulin or glucose but a rise on administration of epinephrine.

The observation that epinephrine will cause a rise in citric acid levels must be taken into account when explaining changes in citric acid levels under certain abnormal conditions. For example, Lövgren claims that high citric acid levels are found consistently in acute allergic states (14).

This may be associated with an increase in epinephrine secretion observed in this condition (15):

Other substances have been reported as causing increased citric acid levels in the blood. Alvall (16) reports an increase in citric acid levels with prostigmine in man. However, Martensson (17) disagrees with these findings and reports no change. Differences of this type which appear in the literature may be due, in part, to variations in the alarm response of patients under the varying conditions under which the experiments were carried out.

Physostigmine, a compound related in physiological action to prostigmine, is reported to interfere with a rise in citric acid levels which normally follows injection of calcium lactate (18). The action of this drug and others like it which lower citric acid levels should be studied in their rela-

tionship to their anti-epinephrine action and their effect on epinephrine secretion.

Of interest is the observation of Hajdu and Korenyi (19) that continuous injection of citric acid will cause hypertrophy of the medulla of the suprarenals. If the left celiac ganglion is extirpated hypertrophy does not occur. The greatest concentration of citric acid in the body occurs in the suprarenals (20-22).

Synthalin, a guanidine derivative, causes a lowering of glucose levels in diabetics. This compound and guanidine itself will produce a rise in citric acid levels when injected (23). In view of our observations that insulin causes a lowering of citric acid levels, it is apparent that synthalin, as far as its effect on citric acid levels is concerned, is quite different from insulin. It is well known that synthalin produces liver damage (24-26). In

severe liver damage elevated citric acid levels have been reported (27).

The exact relationship between citric acid and endogenous epinephrine levels will be ascertained only when a precise and specific method for the determination of minute amounts of epinephrine becomes available.

SUMMARY

Epinephrine administered intramuscularly caused a rise in citric acid serum levels in 28 normal adults and children.

Administration of glucose intravenously or insulin intramuscularly results in a decrease in citric acid serum levels.

STUDIES OF THE EFFECTS OF FLAVONOIDS ON ROENTGEN IRRADIATION DISEASE. II. COMPARISON OF THE PROTECTIVE INFLUENCE OF SOME FLAVONOIDS AND VITAMIN C IN DOGS¹

By JOHN B. FIELD² AND PAUL E. REKERS

(From the Department of Radiation Biology, University of Rochester, School of Medicine and Dentistry, Rochester, New York)

(Received for publication February 22, 1949)

The nature of dietary factors contributing to the maintenance of vascular integrity has not, as yet, been satisfactorily elucidated. However, vitamin C appears to play a specific role (1-3) by functioning in some manner to incorporate the vascular cement substance. The significance of other agents in alleviating "vascular purpura" has remained inconclusive.

It has been claimed that "vascular permeability" is dependent upon regulation by the entire class of "vitamin P" substances. Since 1936, the experimental device of eliminating "vitamin P" from the diet of guinea pigs has been the customary approach with markedly contradictory observations recorded (4-10). Recent investigations in this laboratory have utilized a somewhat different principle in a study of exogenous agents contributing to vascular repair (11, 12). Roentgen irradiation disease in dogs induces a train of pathological phenomena secondary to a generalized cellular disturbance (13). Since a purpura has been an invariable feature of controlled roentgen irradiation, anti-hemorrhagic agents have been considered, but vitamins K, C and the B complex and calcium have proven ineffective (14). When the flavonol glucoside, rutin, was given to 350 r whole-body, single-dose irradiated dogs, not only was the hemorrhagic diathesis significantly reduced, but mortality fell from 60 per cent to 11 per cent (11, 12). The control of purpura was achieved in the presence of marked thrombocytopenia and other typical manifestations of irradiation disease.

Thus, it has been proposed that rutin either decreases the rate of vascular disintegration, or increases its repair (12).

The purpose of this report is to summarize briefly observations on the activity of other substances of the flavonoid and related groups and to indicate the relationship of these substances with vitamin C in the irradiated dog.

METHODS

Dogs of the beagle strain, identical to those utilized in the previous study (12) were used throughout. Diet, the manner of animal care and recording of observations were performed as before. Irradiation and hematological methods have already been described (12). The dosage in all these studies delivered to the dorsum of the skin of the dogs was 350 r. This value was established with each irradiation by a direct trial measurement with the Victoreen ionization chamber.

The most reliable and consistent basis for evaluation of the value of anti-irradiation agents has been a consideration of the end-mortality of treated and control dogs. A statistical analysis with the χ^2 -test indicated the minimum number of dogs required in the testing of an agent to validate a deviation from control mortality. Further, this analysis assisted to establish the significance within a 2-5 per cent probability level. Table I serves to illustrate this consideration. Thus, based on a mortality of 60 per cent amongst 37 untreated control dogs, an experimental mortality of 10 per cent would have a 74 per cent chance of detection and validation when 10 dogs were used in the trial; 53 per cent when six dogs were used. A mortality of 20 per cent would have a 38 per cent chance of detection when 10 dogs were tested, 26 per cent when using six dogs.

In view of the limited supply of test animals and of some scarce compounds, usually five or six dogs were utilized in each trial. Thus, with numbers such as these, significance can only be attached to results indicating a mortality no greater than one dog in each group of five.

Test substances were usually given in single doses of 50 mg. for purposes of direct comparison with results obtained with the same dose of rutin. The compounds were given orally in gelatin capsules three times daily beginning one week prior to irradiation and continuing until 28 days post-radiation. The consumption of these

test substances was facilitated by incorporating the capsule in approximately 10-20 grams of fresh ground beef. The control dogs received an equal quantity of meat three times daily.

EXPERIMENTAL

Biologic response to irradiation

When 37 dogs were given the standard total body single dose of 350 r roentgen irradiation, typical leukopenia, thrombocytopenia and anemia were followed by hemorrhagic signs and gross bleeding in 64 per cent, while 60 per cent of the dogs succumbed in 20 (13-30) days. When the flavonol glucoside, rutin, was administered continually pre- and post-radiation to 27 dogs, 22 per cent developed a purpuric tendency and only 11 per cent died in 21 (16-31) days (Table II). A significant change from untreated controls was a reduction in the hemorrhagic diathesis (11, 12). It has already been noted that rutin had little or no effect upon the panhematopenia of the irradiation disease.

Effect of flavonoids in irradiated dogs

A variety of substances in the flavonoid series have been tested in the standard manner in the 350 r irradiated dog. These include the flavonol glucosides hesperidin,² naringin² and quercitrin,⁴

² Furnished by Mr. A. J. Lorenz, Director of the laboratories, and Mr. W. E. Baier, Manager, California Fruit Growers' Exchange, Ontario, California.

Esculin	6	3	50	15	13-19	100
Quercitrin	9	5	44	16	12-22	78
Naringin	6	3	50	21	17-28	50
Sodium gentisate	5	2	40	19	15-22	80
Dopa	6	3	50	14	12-15	50

obtained with the feeding of rutin are given in Table II to provide some basis of comparison.

In brief, it is to be noted that as observed with rutin, treatment with hesperidin, epimerized d-catechin, homoeriodictyol and morin reduced the incidence of hemorrhage and mortality of the irradiated dogs (Table II). Animals which succumbed from the effects of irradiation were grossly similar whether or not a flavonoid was given; hypoplasia of hematopoietic centers, generalized purpura and visceral hemorrhages were always observed. In general, dogs which survived exhibited fewer and smaller induced petechiae. The results from careful hematological studies can be summarized as follows: averaged values from dogs treated with the substances listed in Table III were identical with those of the untreated dogs while the changes seen in the peripheral blood of dogs given the compounds in Table II resembled those recorded for rutin-treated irradiated dogs (12). In the latter, the significant differences observed were a reduced rate of anemia formation, an increase in erythroblasts and nucleated red blood cells, and a significantly lower sedimentation rate.

Effect of other agents in irradiated dogs

Since flavanones can be degraded *in vitro* to a benzopyrone, it appeared possible that the latter type of compound might retain certain of the anti-irradiation effects of the parent flavonoids. Accordingly, coumarin⁸ was selected as an illustrative compound and tested in the usual fashion. Of six dogs, only two (33 per cent) succumbed 15

(12-19) days after irradiation with some reduction in hemorrhagic tendencies.

In vitro tests (15) have indicated that members of the "vitamin P" group are effective in inhibiting the activity of hyaluronidase. A suggestion was entertained that increased hyaluronidase activity in the roentgen irradiation disease might induce certain features of the vascular dysfunction and "disintegration" (16).⁹ This was fortified by reports that "vitamin P" compounds possessed anti-hyaluronidase activity in *in vitro* tests (15). The recent note of Meyer (17) of potent hyaluronidase inhibitors in the quinoid structures raised the possibility that these substances might also influence the course of irradiation disease. Thus, 3, 4-dihydroxyphenyl alanine (dopa)⁶ and sodium gentisate⁶ were tested in the standard manner and the data are summarized in Table III. Although only two of five dogs (40 per cent) treated with sodium gentisate succumbed, the surviving animals were critically ill. It is to be noted that in so small a test series, the fate of one animal will influence the mortality by 20 per cent. In no significant manner did the hyaluronidase inhibitors influence the course of irradiation disease in dogs.

Effect of ascorbic acid on the anti-irradiation activity of vitamin P compounds

Twelve dogs were given 100 mg. of 1-ascorbic acid orally three times daily beginning one week pre-radiation, and after the standard exposure to 350 r the test substance was given four additional weeks (12). Six dogs (50 per cent) succumbed after 12-14 days post-radiation and the clinical course and hematological data of all animals were identical to the control irradiated dogs (Table IV). Subsequently this treatment, which had been ineffective in itself, was combined with the substances selected from the "inactive" list in Table III. These were hesperidin methyl chalcone and quercitin. Thus, 100 mg. of ascorbic acid plus 50 mg. of hesperidin methyl chalcone were given orally three times daily to five dogs, and 100 mg. of ascorbic acid plus 50 mg. of quercitin were given to 10 dogs. The medication was continuous through-

⁹ In other studies, we have observed that neither irradiation disease nor rutin nor a combination of both, produced an alteration in the urinary excretion of hyaluronidase from the dog. Incubating dog blood with hyaluronidase resulted in no hematological changes.

TABLE IV

Effect of supplementing ascorbic acid with inactive flavonoids on the course of irradiation disease

	Number of dogs		Mortality	Survival post-radiation		Exhibiting gross bleeding
	Started	Survived	per cent	Average days	Range days	per cent
Control	37	15	60	20	13-20	64
Ascorbic acid*	12	6	50	13	12-14	100
Ascorbic acid plus quercetin	10	9	10	11	—	70
Ascorbic acid plus hesperidin methyl chalcone	5	1	80	19	17-21	80

* 100 mg. by mouth given three times daily beginning seven days before irradiation and thereafter for 28 days.

out in the usual manner from one week pre-radiation to four weeks post-radiation. The results of these tests are summarized in Table IV. The hematological data from all groups listed in this table were very similar.

DISCUSSION

It has been suggested that the inconsistencies in the past studies on "vitamin P" have arisen primarily because the need for this agent is not easily demonstrated under normal physiologic circumstances. Another complication encountered has been the derivation of an adequate diet free of the universally distributed flavonoids. A further deterrent has been an ignorance of the species requirements for "vitamin P." Certainly, the latter has been a formidable obstacle in the program of this laboratory and to date, consistent data have been obtained only with the dog but not with the rabbit, rat, guinea pig or mouse.¹⁰

The technique of acute whole-body, mid-lethal irradiation in the dog produces predominantly a vascular derangement detectable most directly in the clinical course of the animal. Autopsy has demonstrated the existence of multiple widespread vascular lesions although the usual histopathological examination of vessels in the irradiated tissues has not revealed the origin of the disintegration. The nature of a true "vascular purpura" is discussed by Hiramatsu (18). He differentiates this

state from a "purpura of the blood" which includes a thrombocytopenia and presumably the existence of any anticoagulant such as heparin (14).

In the course of these studies with the flavanones it has been observed that neither is the course of the usual post-radiation panhematopenia and severe thrombopenia altered significantly by protective flavonoids, nor has it been observed that these agents inhibit heparin.¹¹ Thus, it might appear that these agents affect the vascular system directly, perhaps participating as a principal in the "wear and tear" of a part or all of the vascular system, inhibiting its degeneration and either stimulating, or being incorporated in, its regeneration. In support of this proposition is the observation that the process of vascular disintegration together with universal cellular catabolism and necrosis are accelerated in the irradiated animal. It appears that the "strain" of repair elicits the positive anti-hemorrhagic effects of the flavonoids in the mid-lethal irradiated dog when the usual dietary complement of these agents becomes inadequate.

"Vitamin P" has been identified as a wide variety of flavonoid compounds in the past (4, 5, 19-21). Claims of activity have been made for many of the substances included in the present report. Eventually our present program envisions the "screening" of an even larger number of compounds with the dog irradiation technique and the results of these tests will be given on subsequent occasions. However, it appears that the following flavanones possess in common, an approximately equal capacity to protect the 350 r x-irradiated dog; they are rutin, hesperidin, epimerized d-catechin, homooriodictyol and morin. It is quite possible that there exists a considerable qualitative and quantitative variation of anti-hemorrhagic capacity amongst these substances. However, it would be hazardous to draw anything but limited conclusions from the present data. The purpose of this report is simply to identify compounds which have "protected" the irradiated dog under given specific conditions.

Since the "active" agents possess the same fundamental flavanone structure it appeared incon-

¹⁰ Field, J. B., and Rekers, P. E. To be published.

¹¹ Heparin will increase the sedimentation rate of blood, and although rutin *in vivo* and *in vitro* reduces increased sedimentation rates, it does not affect the prolonged coagulation time of heparinized blood.

sistent that other very similar compounds and flavonol glucosides as quercitrin and naringin failed to influence the course of irradiated dogs. Particularly disappointing was the performance of quercitin, the aglucone of rutin. With the latter substance only 11 per cent of the dogs succumbed to the effects of irradiation. Given quercitin, 50 per cent of the dogs died with severe irradiation disease. Thus, the demonstration of the synergistic action of ascorbic acid when given concomitantly with quercitin, which reduced mortality to 10 per cent, is of considerable interest. The inter-relationship of vitamin C and "vitamin P" has been sharply debated. Zilva (8) indicated that ascorbic acid alone would maintain capillary repair while Szent-Gyorgyi suggested that ascorbic acid probably exerts a catalytic effect potentiating the action of "vitamin P." The present data support the latter view and it may be predicted that supplementary treatment with ascorbic acid may potentiate an anti-hemorrhagic action of other flavanones as naringin and quercitrin reported at present as "inactive." Study of this problem is in progress.

Apparently degradation of the parent flavanone molecule sacrifices anti-hemorrhagic activity. Thus, esculin and hesperidin methyl chalcone failed to "protect" irradiated dogs even when ascorbic acid supplemented the chalcone in one test. These findings are in disagreement with reports of high "vitamin P" activity for these substances as derived through indirect assay methods (20, 21), or when petechiae formation was measured in rats with a thrombocytopenia resulting from treatment with an anti-platelet serum (22). Two of the six dogs (33 per cent) given coumarin succumbed compared with a mortality of 60 per cent in untreated dogs. Until a larger series of dogs is tested, this result cannot be interpreted as any more than a suggestion that a molecule smaller than the flavanones may "protect" irradiated dogs.

The possibility that the "spreading factor," hyaluronidase, plays a role in the course of roentgen irradiation disease and may be implicated "in accentuating capillary fragility rather than inducing direct change in capillary permeability" (16) appears unlikely. This impression is supported by the failure of potent hyaluronidase inhibitors as dopa and sodium gentisate to influence the course of irradiation disease. Contrary to other

claims (15) that "vitamin P" inhibits hyaluronidase, neither has the administration of large quantities of flavonoids had any effect on the hyaluronidase-levels in the urine of the normal dog nor have preliminary tests implicated hyaluronidase in the evolution of roentgen irradiation disease of dogs.

SUMMARY

1. Exposed to 350 r single-dose, total-body x-irradiation, 60 per cent (22 of 37) untreated control dogs succumbed with a prominent hemorrhagic syndrome. Five flavanone substances appeared roughly of equal activity in reducing the hemorrhagic signs of the irradiation disease when administered continuously pre- and post-radiation. When rutin was fed, 11 per cent (three of 27) of the dogs succumbed; with hesperidin, 17 per cent (one of six); with epimerized d-catechin, 10 per cent (one of 10); and with homoeriodictyol none of five and with morin, none of six irradiated dogs succumbed.

2. Other flavonoids and their derivatives did not significantly reduce either the mortality or hemorrhagic changes in irradiated dogs. These included hesperidin methyl chalcone, esculin, quercitrin, quercitrin and naringin. With the benzopyrone, coumarin, 33 per cent (two of six) of the dogs succumbed suggesting slight anti-irradiation activity.

3. Ascorbic acid alone failed to influence the course of irradiation disease and 50 per cent (six of 12) of treated dogs died. However, when ascorbic acid was given simultaneously with quercitrin which by itself was ineffective (50 per cent mortality), only 10 per cent (one of 10) dogs succumbed exhibiting reduced signs of the disease. No increase in protective activity occurred when ascorbic acid and hesperidin methyl chalcone were given together.

4. It is suggested that previous misunderstanding of the nature of "vitamin P" has arisen from both the failure to recognize that several flavanone analogues possess very similar anti-hemorrhagic "activity" and that ascorbic acid has the capacity to potentiate "activity" in other flavanones.

5. Potent hyaluronidase inhibitors as dopa and sodium gentisate failed to influence the course of irradiation disease in dogs. It is suggested that the "spreading factor," hyaluronidase, plays little or no role in the evolution of this disorder.

THE PLASMA VISCOSITY IN PULMONARY TUBERCULOSIS AND RHEUMATIC DISEASES

By JOHN HOUSTON, R. B. WHITTINGTON, I. C. COWAN, AND JOHN HARKNESS

(From the Crossley Sanatorium, Frodsham, England, and the Arthritis Clinic of the Royal Infirmary, Sunderland, England)

(Received for publication October 1, 1948)

INTRODUCTION

In 1940 T'ang and Wang (1) measured the erythrocyte sedimentation rate and the plasma viscosity in 176 cases of pulmonary tuberculosis and 56 cases of tuberculosis of other organs. These writers concluded from their data that the plasma viscosity determination may be a more sensitive test for activity of tuberculosis than the sedimentation rate.

Independently, in 1942, Whittington (2) in a study of the mechanics of the erythrocyte sedimentation rate suggested that this procedure might with advantage be replaced by plasma viscosity measurements.

The method was tried on 63 tuberculous patients by Miller and Whittington (3) who found that the plasma viscosity was a more reliable index of the clinical condition than the erythrocyte sedimentation rate. The general findings of the latter paper were confirmed by Houston, Harkness and Whittington (4) and by Harkness, Houston and Whittington (5) after 645 estimations of the plasma viscosity—223 of these were of pulmonary tuberculosis; 385 were of a variety of diseases and 37 were of normal persons. Although these data indicate that the plasma viscosity is significant in following the course of persons with pulmonary tuberculosis, they show emphatically that the test is non-specific.

For the past 20 years the accepted laboratory method of estimating the general reaction of rheumatic diseases has been the erythrocyte sedimentation rate. From this earlier experience, a trial of the plasma viscosity test in rheumatic diseases also seemed desirable. Cowan and Harkness (6) have reported 320 viscosity estimations made at the Royal Infirmary, Sunderland, in various rheumatic diseases. They found that the viscosity test was much more reliable than the erythrocyte sedimentation rate, and that the measurements of

viscosity appeared to be a promising method of investigation in rheumatic diseases.

Woodmansey and Wilson (7) have reported similar findings. While Race (8) believes that in the more severe clinical conditions the plasma viscosity test is superior to the erythrocyte sedimentation rate, he considers that the erythrocyte sedimentation rate may be the more sensitive in detecting the earliest changes in rheumatic disease.

The statistics of the present paper are based on the results obtained up to the end of February 1948, at Sunderland, and to the end of December 1947, at the Crossley Sanatorium (Table I).

So far as we know, the subject of plasma viscosity has not yet been discussed in the American literature: our results are, therefore, presented in order that readers in the United States can form an opinion on what we consider to be the most useful of the physical, non-specific laboratory estimations.

METHODS AND MATERIALS

I. Methods

The type of viscometer that we have used throughout our tests is accurate to about one part in 500, and requires only about 0.7 ml. plasma for each test. This is the Whittington viscometer, of which a full specification has already been published (4), together with the details of calibration and operation. Like the original large-capacity Ostwald type of instrument (of which it is a modification) this viscometer requires a waterbath and a stop-watch as additional apparatus.

As anticoagulants, our experience with sodium citrate solution, potassium oxalate, mixed oxalates and heparin leads us to believe that the present choice lies between the 3.8% aqueous solution of sodium citrate (1 volume solution: 4 volumes blood) and the Heller and Paul mixture (9) of potassium and ammonium oxalates as used for the Wintrobe erythrocyte sedimentation rate.

The range of normality with 3.8% sodium citrate solution is both absolutely and relatively narrower than with oxalate; thus the differentiation between normal and pathological is easier with the citrate technique. It has the disadvantage that the proportion of citrate solution to plasma depends on the volume of erythrocytes present since a given volume of whole blood is added to a fixed

† 27 tests were performed using both Sodium Citrate and Mixed Oxalates.

volume of citrate solution. It is therefore necessary to make an accurate hematocrit estimation followed by an empirical correction to the observed plasma viscosity, so as to allow for the proportion of citrate solution diluting the plasma in a given case.

The oxalate results are satisfactory for most clinical purposes. As the volume of blood to be added to the prepared bottle is not critical, it is certainly the method of choice where the collection of blood is undertaken in imperfect conditions, such as in a busy out-patient department. Also, it is convenient to estimate the plasma viscosity on a portion of a sample of blood removed for other hematological investigations.

When examining such colloidal solutions as plasma, serum, etc., the "viscosity" value depends on the dimensions of the particular individual viscometer. The differences between two viscometers with the same plasma may be considerable. It is essential therefore to standardize the viscometers to a common standard. The methods of standardization have been discussed elsewhere (4, 10).

Quarter-ounce (7 ml.) capped bottles are prepared for 5 ml. of blood by evaporating in an incubator 0.2 ml. of an aqueous solution containing 2% potassium oxalate and 3% ammonium oxalate. Five ml. (± 0.5 ml.) of venous blood, drawn with minimal stasis, is added. The contents are mixed by gentle rocking to avoid the formation of froth. In the laboratory the blood is centrifuged to separate the plasma. One ml. of the plasma is pipetted into a small evaporating dish, the viscometer is filled, and the viscosity is estimated as detailed previously (4). While it is preferable to complete the estimation as soon as possible, serial testing has shown that delay of as much

as five days in some instances has not altered the viscosity results.

When sodium citrate is used as the anticoagulant, 2 ml. of a 3.8% aqueous solution is pipetted into a 10-ml. volumetric flask or a centrifuge tube graduated at 10 ml. Venous blood is added exactly to the mark and gently mixed. A sample is removed for hematocrit estimation. The remainder is treated as for the oxalate blood above. An empirical correction has to be applied to this viscosity to make allowance for the variation in the plasma-citrate mixture due to anemia. A nomogram for this correction has been published (4).

On the basis of the complicated inter-relationship of the citrate plasma viscosity to the maximum citrate erythrocyte sedimentation rate the viscosity range has been divided into 11 zones. These zones are of special interest with reference to pleural effusions. The limits of the zones are in Table II.

II. Patient Material

(a) *Tuberculous patients*: Clinical grouping of the patients is based on a recent Ministry of Health circular (11) which can be briefly summarized as follows:

A-category: patients in whom tubercle bacilli have never been discovered.

B-category: patients in whom tubercle bacilli have been demonstrated at some time.

Each category is subdivided as follows:

Group 1. Slight or no constitutional disturbance: physical signs and radiological findings of very limited extent: no complications (tuberculous or other) of prognostic gravity.

TABLE II

Non-articular rheumatism	16 (10)	1.725-1.950 (1.725-1.950)	1.888 (1.896)	45.3 (46.3)	7.8 (6.7)	7.23 (7.34)
Still's disease	7	2.050-2.850	2.352	34.2	45.0	8.01
Gout	11	1.800-2.300	2.051	44.0	23.8	7.65
Atrophic spondylitis	14	1.750-2.300	1.983	44.1	13.0	7.40

* The figures within the parentheses are the statistics for the first 320 tests in Rheumatic Diseases, as previously published (Cowan and Harkness [6]).

† Rheumatoid arthritis—synonym, Atrophic polyarthritis.

‡ Infective polyarthritis (atrophic)—cases of atrophic polyarthritis where there is a definite focus of infection, e.g. in a nasal sinus, which is related to the arthritic condition.

§ Chronic osteo-arthritis—synonym, Hypertrophic, degenerative osteo-arthritis.

|| Non-articular rheumatism—synonym, Fibrositis, Bursitis, Panniculitis, Periarthritis, Myalgia, etc.

Group 3. Profound systemic disturbance or constitutional deterioration, and marked impairment of function, either local or general. All cases with grave tuberculous or non-tuberculous complications are placed in this group.

Group 2. All cases which cannot be placed in Group 1 or Group 3.

The Ministry of Health grouping is made on admission and it is not established practice to revise downward any such grouping in the case of a recovering patient. However, an A-category patient would be transferred to the B-category if tubercle bacilli were demonstrated at any time during the course of treatment.

(b) *Rheumatic patients*: These patients were classified as in Table III under "condition."

RESULTS

I. In Tuberculosis

Figure 1 shows the distribution of average viscosities in 330 tests on 289 individuals (including 37 controls). During the period since our last publication of results for pulmonary tuberculosis (4) we have performed 275 viscosity tests on tuberculous patients.¹

When interpreting Figure 1, it must be borne in mind that the viscosity values are only averages. If, for example, a sufficient number of B.2 sana-

¹ All results in this part are for citrate plasma.

FIG. 1

torium cases be tested, the average of their viscosities will probably be found to be about 1.746. Nevertheless, the graph shows how, on the whole, the viscosity increases with the spread of disease, since the average viscosities rise fairly steadily from the normals to the most advanced (B.3) category.

The graph does not show, of course, how the viscosities of recovering patients ultimately return

to the normal range, but we now have sufficient experience to be able to state definitely that this is so in the patients discharged without physical signs.

Where the disease ends fatally, we have observed a terminal phase in which the final advances of the disease are accompanied by a fall in viscosity towards the normal range. This phenomenon has been termed "terminal decay."

In Figure 2 we show the distribution according to the citrate plasma viscosity zones of those cases with definite clinical and radiological evidence of the production of clear pleural fluid at the time when the blood was removed for the test. Forty-two tests on 32 patients are given: 22 (52%) are

in viscometric zone 7 (1.762 to 1.832), and 32 (76%) are in zones 6 to 8. These results suggest that zones 6 to 8 form a region in which it is highly probable that exudative cases will lie.

It has been our experience that if a pleural effusion be aspirated while the viscosity is in zone 7,

FIG. 2

the fluid reforms at once. In other cases whose viscosities are either above or below zones 6 to 8, fluid does not reform after aspiration, although if, later, the viscosity should return to the critical region, the fluid may reform.

No physical explanation of this phenomenon can yet be attempted; but it appears to be of potential importance in the management of pleural effusions, especially as a complication of artificial pneumothorax.

(SHOWN AGAINST CLINICAL SEVERITIES) IN RHEUMATOID ARTHRITIS.

FIG. 4

It is of interest to report that in our only case of tuberculous pericarditis the fluid was formed when the plasma viscosity was in the critical zone 6 to 8 range.

II. In Rheumatic Disease ²

From our experience with more than 750 tests in rheumatic disease, the results can be summarized as follows:

(a) In every case in which the plasma viscosity was raised to an abnormal level (above 1.950) an underlying organic cause was ultimately found.

(b) In rheumatic fever, the plasma viscosity increased as the disease progressed and decreased during recovery. If, during recovery, the nature of the disease process changed from an acute to a chronic type, the change was shown by the cessation of fall or even by a rise in the plasma viscosity; the viscosity was a more sensitive index of this change than the temperature, pulse or erythrocyte sedimentation rate.

(c) In rheumatoid arthritis the increase in the plasma viscosity was roughly in proportion to the severity of the pathological changes in the locomotor system and to the systemic reaction.

The viscosity values changed with variation in the clinical condition. It required but slight changes clinically to produce significant alterations in the viscosity. With clinical improvement the viscosity values approached those found in normal persons.

In many instances where the plasma viscosity was raised, the erythrocyte sedimentation rate was within normal limits, yet clinically the disease process was active. Conversely, in many cases where residual deformity remained and there was no other indication of systemic upset, the erythrocyte sedimentation rate remained elevated while the viscosity had returned to the normal range.

Figures 3 and 4 present graphically the results given in Table III, indicating the increase of the plasma viscosity with increasing severity of the disease. Figure 4 emphasizes the inability of the

² All results in this part are for oxalate plasma.

erythrocyte sedimentation rate to differentiate between subacute and acute conditions.

(d) In cases of non-articular rheumatism where there appears to be no systemic reaction, the plasma viscosity values remain within normal limits.

(e) With chronic hypertrophic osteo-arthritis, there were indications of little or no systemic reaction and this was reflected in the viscosity results.

(f) The findings of the other groups of the rheumatic diseases are given in Table III and Figure 3.

CASE HISTORIES

I. Tuberculosis

Case C. 280, a female, aged 30, was admitted to the Crossley Sanatorium on July 23, 1946, with extensive tuberculous infiltration of the upper third of left lung, with cavitation, and slight infiltration of right outer infraclavicular region.

This patient received routine sanatorium treatment for two months, resulting in improved general condition. Left artificial pneumothorax was induced (Day "minus 38"—chart reference). Following persistent nose-bleeding, the blood-clotting time was estimated and found to be considerably above normal. She was given 60 mgs. water-soluble Vitamin K analogue daily (Day "11"). At routine screening of the chest a minimal effusion in the left costo-phrenic angle was noted (Day "minus 4").

The various laboratory tests carried out, beginning at Day 0, are plotted in Figure 5. Day 81, left internal pneumolysis: three band-adhesions found, two divided and one to the third rib partially divided. On Day 122, the effusion had spontaneously cleared, the cavity remained patent. On Day 214, second internal pneumolysis: as much as possible of the third adhesion was divided. Left effusion developed at once after operation; and 60 ml. of clear fluid were aspirated on Day 221. This left a very small effusion in the costo-phrenic angle, which had cleared spontaneously by Day 269. The cavity was closed by Day 293 and thereafter clinical progress was uneventful.

SERIAL TESTS ON A TUBERCULOUS PATIENT

FIG. 5

This case illustrates several points which we feel are worth discussing. A glance at the chart shows three obvious peaks. All three peaks have definite clinical significance. Peaks 1 and 2 are related to internal pneumolysis, while the third peak is probably a reaction to increasing hours of exercise.

A most interesting feature of peak 1 is that the rise in viscosity was first noticed on Day 73, eight days before the operation, and this rise continued steeply on Day 77, as shown. The patient was informed some time between Days 69 and 73 that adhesion-section would be performed on Day 81; and fear of the proposed operation is suggested as the cause of the pre-operational rise. A similar explanation is offered for the pre-operational rise at peak 2.

In support of these observations, we would refer to the findings of Macfarlane and Biggs (12) who have investigated the occurrence of fibrinolysis associated with trauma. They found that in some cases "fear of impending operation" appeared to cause positive results. They also drew attention to parallel observations made by Latner (13) who recorded fibrinolysis in normal subjects during air-raids.

We feel that the rise shown by the last few readings may also have a psychological explanation, since the patient was notified on Day 374, after many months of sanatorium sojourn, of her actual "discharge date."

These phenomena appear to show that the plasma viscosity can be an extremely sensitive index of a patient's condition.

The occurrence of pleural effusion is shown hatched on the viscosity chart. The initial effusion was observed at Day "minus 4," so that we have no record of the viscosity reading at the time of production of fluid. The amount of fluid present as observed radiologically did not appear to increase after Day 0, despite the fact that the plasma viscosity passed through zones 6 to 8 prior to and following the pneumolysis. Later, however, as the viscosity fell further the effusion cleared spontaneously by Day 122. From this point until the second pneumolysis, the pleural cavity remained dry. Immediately after this operation when the viscosity was within zones 6 to 8, a second effusion occurred. This was aspirated on Day 221 when, according to the graph, the viscosity was in zone 5; and apart from the small residuum left at aspiration, no further accumulation of fluid took place. By Day 269, the pleural cavity was dry.

II. Rheumatic Diseases

1. Acute Rheumatic Fever. Three weeks before admission to the hospital, B. R., a male, aged 42 years, had a sore throat which was followed eight days later by elevated temperature, joint pains and other evidence of a classical attack of acute rheumatic fever. Salicylates were administered in doses sufficient to cause buzzing in the ears, with only partial response. The patient was admitted to the hospital on July 22, 1947.

Sodium salicylate internally and methyl salicylate locally to the painful joints were continued until August

13, 1947, when the sodium salicylate was discontinued (because of toxic symptoms) and replaced by calcium aspirin. The plasma viscosity and the erythrocyte sedimentation rate on August 12, 1947, showed a moderate reaction. The alteration in treatment was followed immediately by an acute recurrence of joint pains, elevation of temperature, sweating, etc., and this worsening was reflected in the increase of viscosity of August 18, 1947, while the erythrocyte sedimentation rate showed an appreciable reduction.

On August 17, 1947, the sodium and methyl salicylate were resumed. On August 23rd, while the patient was receiving large prophylactic doses of penicillin, some decayed teeth were removed. Thereafter improvement was continuous until his discharge on September 11, 1947 (to rest at home). Again the improvement was reflected in the plasma viscosity changes; the erythrocyte sedimentation rate rose inexplicably on August 25th, thereafter also mirroring the clinical improvement.

Date	P.C.V. (%)	Plasma viscosity	Plasma protein (g./100 ml.)	Maximum citrate E.S.R. (mm./hr.)
8-12-47	41.2	2.186	7.34	55.7
8-18-47	38.5	2.228	7.13	41.2
8-25-47	39.0	2.183	7.42	43.5
9- 4-47	41.4	2.107	7.24	35.1
9-11-47	41.3	1.997	6.91	28.8
1- 9-48	47.2	1.895	6.95	7.4

When the patient reported three months later to the out-patient department both tests had returned to normal values; there was no clinical indication of activity; there was no evidence of cardiac involvement by the disease.

The plasma viscosity here appears to be a useful index of the pathological processes occurring in the patient.

2. Chronic Rheumatoid Arthritis. O. G., a female, aged 25 years, gave birth to a normal healthy baby in July, 1946. Three months later she began to complain of pain and stiffness of the small joints of the fingers, and then of a tendency towards ulnar deviation of the fingers at the metacarpo-phalangeal joints. Gradually pain and swelling developed in both knees, and there was swelling of the right ankle joint.

There was fusiform swelling of the small joints of the fingers, ulnar deviation at the metacarpo-phalangeal joints, periarticular thickening of both wrists with limitation of dorsiflexion of the right wrist; both knees were hot and swollen, and there was limitation of flexion of the right knee by 20°; the right ankle was "puffy" and painful, although there was full range of movement. General medical examination revealed no focus of infection; urine showed no abnormality; skiagram of chest was negative. Skiagrams of the involved joints showed changes typical of rheumatoid (atrophic) arthritis. The picture was typical of a case of chronic rheumatoid arthritis of some months' duration.

She had been confined to bed at home for eight months prior to admission to hospital on July 2, 1947, when her blood test gave the following results:

Date	P.C.V. (%)	Plasma viscosity	Plasma protein (g./100 ml.)	Wintrobe E.S.R. (mm./1st hr.)
7-2-47	41.2	2.117	7.54	—

Treatment consisted of rest in bed, active physical therapy, procaine and lactic acid injections (Waugh [14]) to the affected joints, and a course of gold injections (myocrisin). She improved slowly, and by August 20, 1947, she was reported to be capable of standing alone and walking with assistance. The improvement was reflected in her next result:

9-9-47	39.6	2.038	7.45	—
--------	------	-------	------	---

Treatment was continued. Ferrous sulphate tablets were given to combat the anaemia. Improvement was continuous; and she was discharged on September 30, 1947, walking unassisted.

9-30-47	40.4	1.974	7.16	—
---------	------	-------	------	---

Three months later, at the beginning of December, she had an attack of influenza. This was followed by a flare-up of all the involved joints. The condition had deteriorated from one of temporary quiescence to one of marked activity, the change being shown also in the laboratory results.

12-22-47	43.4	2.326	8.46	28
----------	------	-------	------	----

The patient rested in bed and a further course of physical therapy and myocrisin was given. At the end of the course the pain in the joints had diminished, and weight-bearing was again possible.

3-9-48	39.3	2.103	7.70	40
--------	------	-------	------	----

The clinical impression at that time was that the disease condition was being controlled; the fall in the plasma viscosity supported this contention, in spite of the rise in the erythrocyte sedimentation rate. Out-patient treatment was continued. Unfortunately, on June 28th, she reported pain in the right hip which had not been affected previously; a skiagram of this joint showed changes typical of atrophic arthritis. The plasma viscosity reflected this increase in the activity of the disease, in keeping with the involvement of a new joint (a major one). On the other hand, the erythrocyte sedimentation rate decreased.

7-1-48	42.9	2.213	8.35	32
--------	------	-------	------	----

3. *Chronic Hypertrophic Osteo-arthritis.* K. M., a female, aged 50 years, gave a history of pain and stiffness in both knees of six weeks' duration. She had had no other illnesses in her life and no history of injury was given.

There was marked periarticular thickening of both knees, and considerable quadriceps wasting. There was no increased local heat and no synovitis. Her fingers showed Heberden's nodes. Skiagrams of the knees showed the appearance typical of chronic hypertrophic osteo-arthritis. Her laboratory results were:

5-22-47	37.9	1.871	7.45	10
---------	------	-------	------	----

Here, as is usually the case in chronic hypertrophic osteo-arthritis, the plasma viscosity was within normal limits.

4. *Non-Articular Rheumatism.* J. H., a male, aged 34 years, had chronic fibrositis of the upper back almost continuously following rheumatic fever at the age of 17 years. July 17, 1948, after three days in which an acute flare-up made it impossible for him to move his head or shoulders without acute pain, his laboratory findings were:

Date	P.C.V. (%)	Plasma viscosity	Plasma protein (g./100 ml.)	Wintrobe E.S.R. (mm./1st hr.)
7-17-48	45.2	1.849	7.31	—

DISCUSSION

The plasma viscosity test is non-specific. We feel, however, that it is valuable in following the progress of various rheumatic diseases as well as pulmonary tuberculosis. It depends almost entirely on changes in the plasma protein (especially the fibrinogen and globulin fractions), since ultrafiltrate experiments have shown that the viscosity of the ultrafiltrate fluid is practically constant.

If the liver is regarded as the organ which is chiefly responsible for the formation of these plasma proteins then the plasma viscosity is a measure of a change in a liver function, in response to a disease process in the body.

It is not surprising that in pulmonary tuberculosis the systemic reaction and hence the plasma viscosity should parallel the severity of the disease process. In rheumatoid arthritis also the plasma viscosity varies directly with changes in the joints and soft tissues. This emphasizes the general nature of rheumatoid arthritis and the fact that the changes in the joints are only one part of the whole disease process.

In striking contrast are the findings in hypertrophic osteo-arthritis—a localized condition with little systemic reaction—where marked changes can occur in the joints with very little alteration in the plasma viscosity. Similar conclusions can be made for the other rheumatic diseases. In non-articular rheumatism there is an absence of systemic reaction; and little change in the plasma viscosity. Increased viscosity does occur, however, in such systemic diseases as gout, Still's disease, infective polyarthritis² and atrophic spondylitis.

Since the plasma viscosity is affected only by the plasma proteins, the question arises as to whether it would not be more accurate and informative to

² See footnote, Table III.

measure the proteins themselves. Consideration of Table III and the individual case histories will show that the total plasma protein is not so sensitive or reliable an indication of the clinical changes as the plasma viscosity. The estimation of the plasma viscosity is technically much simpler and less open to error than the estimation of the protein fractions. Our experience with over 250 parallel estimations of the plasma viscosity and protein fractions has indicated clearly that the viscosity test is by far the more sensitive; the viscosity may have reached definitely abnormal levels when the fractions are still within the usual range of normal values. It is possible to find abnormal protein fractions associated with a normal viscosity, but many of these are cases of terminal decay, to which reference has already been made: in this instance, protein fractionation may be more informative than the viscosity test.

We have not been able to detect any uniform plasma protein pattern associated with plasma viscosities in zones 6 to 8, where pleural effusions tend to form. In addition to this zone there is another of great clinical significance which cannot be detected readily by protein fractionation. Into the range of 2.025 to 2.175 (oxalate) fall the majority of cases who are suffering from chronic conditions of all types—rheumatic fever, rheumatoid arthritis, infective polyarthritis, syphilis and pyogenic infections. If in the course of a disease two viscosity values, at a few weeks' interval, fall into this zone, it is highly probable that the disease is of a chronic nature; we have noted this happening on several occasions during recovery from acute rheumatic fever when the condition has taken on a chronic nature. The importance of the ability of the test to detect a change from an acute to a chronic process need not be stressed from the aspect of prognosis and treatment.

Although the plasma viscosity test and the erythrocyte sedimentation rate may both reflect changes in the plasma proteins, the results of the two tests may be dissimilar. Careful correlation of the results of these tests with the clinical condition has shown that the plasma viscosity is not only the more reliable but that the erythrocyte sedimentation rate can be definitely misleading. The superiority and the reliability of the plasma viscosity test become very obvious when individual patients have serial examinations during

the course of their illnesses. While it must be admitted that in some cases with clinically apparent early disease the erythrocyte sedimentation rate will begin to rise before the plasma viscosity starts to change, there have been instances in which an abnormally high erythrocyte sedimentation rate has been found in an apparently normal person and no cause for this increase has ever been found. In contrast is our experience with over 2500 plasma viscosity tests where in every case of a high viscosity value the cause of this increase was ultimately detected.

CONCLUSIONS

1. The plasma viscosity has been estimated in 656 tests on cases of pulmonary tuberculosis and in 750 tests on cases of rheumatic disease.
2. The results have been considered generally and some representative cases have been given in detail.
3. The plasma viscosity test is not specific. It depends on changes in the plasma proteins.
4. The plasma viscosity indicates systemic reaction to disease processes.
5. As an indication of the presence of and changes in the systemic reaction the test is sensitive and reliable.
6. The systemic reaction (and hence the plasma viscosity) mirrors the changes in the local lesions in pulmonary tuberculosis, rheumatic fever, and rheumatoid arthritis.
7. The formation of pleural effusions is usually associated with plasma viscosities within a narrow range of values.
8. Chronic disease processes are also associated with a narrow range of viscosity values.
9. The value of the plasma viscosity test to the clinicians treating pulmonary tuberculosis and rheumatic diseases is discussed.

PROCEEDINGS OF THE FORTY-FIRST ANNUAL MEETING OF THE
AMERICAN SOCIETY FOR CLINICAL INVESTIGATION
HELD IN ATLANTIC CITY, N. J., MAY 2, 1949

READ BEFORE THE SCIENTIFIC SESSION

PRESIDENTIAL ADDRESS

CLINICAL RESEARCH AS A CAREER

By WESLEY W. SPINK

On May 10, 1909, Dr. S. J. Meltzer, the first President of this Society, addressed the members on the subject, "The Science of Clinical Medicine: What it Ought to be and the Men to Uphold it." In his introductory remarks he said, "The honor of the presidency of a society goes with the privilege of discussing some of the aims of that society." In discharging my responsibility as President, forty years after Dr. Meltzer, I am tempted to review the accomplishments of this Society, but such would be idle boasting. I would like to call your attention to the history of this Society by Dr. J. Harold Austin of Philadelphia which appears in the March, 1949 issue of the *Journal of Clinical Investigation*. It is well worth reading. Dr. Meltzer was deeply interested in the capable young individual who elected a career of clinical research. Since today, more than ever, young individuals are continuing to manifest an interest in clinical investigation, I would like to discuss with you some of the problems relating to their training.

The Clinical Investigator as a Clinician

Clinical investigation implies the critical study of human beings in sickness and in health. This suggests many ramifications of effort. While fruitful studies on human disease may be pursued within the confines of laboratory walls without the investigator ever coming in contact with patients, someone has had to define the problem or problems in disease that the patients present. It cannot be emphasized too strongly in this day of highly specialized techniques and laboratory research that successful clinical investigation is dependent upon a knowledge of disease in human beings. If one is setting out to resolve a problem in human disease, it is desirable to know as much as possible about the natural history of that disease. This information is not to be gleaned in an armchair, pouring over books and journals, but rather by the persistent observation of patients on the wards and in the dispensaries. The individual interested in a career of investigation should pursue further clinical training after completing his internship by selecting an appointment in which he will be given responsibility for the care of patients and in an institution where he will have the time and facilities to engage in research. Competent advisors should be readily available to aid him in his clinical activities and to lend direction to his investigations.

What attitude should the resident in clinical medicine interested in a career of research and academic medicine take toward certification by one of the specialty boards

of medicine? This is not the place to discuss the trend toward specialization in medicine as reflected by the specialty boards. But I see no valid reason why the resident should not fulfill the requirements of certification while he is obtaining his training. If he expects some day to have an academic appointment of any merit, in which he will be responsible for the clinical training of undergraduate and graduate medical students, he should at least possess that general knowledge of medicine which is necessary to pass the examinations of a specialty board. Furthermore, after he has had his formal residency training and has had an opportunity to engage in research activities, he may desire to go into the practice of medicine, or, much against his wishes, economic circumstances and obligations may make it mandatory that he enter into care of his own patients. Engaged in the private practice of medicine as a highly trained clinician, certification by a specialty board will be a decided advantage. However, it is difficult to lend a sympathetic ear to the individual whose primary interest in a residency is to fulfill the requirements of a specialty board and who applies for an appointment on a service devoted to teaching and clinical investigation with this purpose in mind.

The Clinical Investigator and the Basic Sciences

Clinical investigation today, contending as it does with the complexities of human disease and the assimilation of quantitative information, has narrowed the possibilities of carrying out fundamental research at the bedside of the patient. Highly technical knowledge is essential and the special tools of a basic discipline are frequently needed. The clinician may obtain help with his problem by turning to his colleagues in the basic sciences or to skilled laboratory technologists. Under these circumstances, he throws himself on the mercy of others for the accuracy of the acquired data and for their interpretation. It is difficult to evaluate laboratory results if one is unacquainted with the basic principles involved, and one cannot seek out the sources of error if he is ignorant of laboratory methods. Therefore, in the prosecution of clinical research, it is frequently necessary for the clinician to take time out and go into the laboratory. A year or two may be devoted to one of the basic sciences such as physiology, bacteriology, or pharmacology. Today it is not unusual for clinicians to concentrate on a review of the advances in the fields of chemistry or physics. A brilliant chapter in the history of clinical investigation includes modern cardiovascular surgery

achieved by the amalgamation of basic physiologic principles and improved surgical techniques worked out in the laboratory on lower animals. The surgical correction of coarctation of the aorta was not evolved by the method of trial and error on human subjects, but the techniques emanated from the laboratory after months of painstaking thought and effort.

The Clinical Investigator and the Research Team

One of the developments in recent years in clinical research has been the organization of personnel as a team in the prosecution of a problem. This tendency toward joint effort was accelerated during the last war. For many projects there are distinct advantages that accrue from pooling the abilities of several investigators. Among the disadvantages lurking in such an endeavor is the shackling of the independence of thought and initiative of young investigators. Any individual who wants to do original work in clinical research must be extremely discriminating in electing to participate in a large project lest his freedom of thought and action be smothered by the desires of his supervisors. This trend toward team research applies not only to the medical sciences but also to other fields.

The Clinical Investigator and the Preparation of Data for Publication

It is unfortunate that many investigators in the course of their training have not been given direction in communicating their results to others. While this applies also to the verbal presentation of data, I am particularly concerned with the preparation of manuscripts for publication. Such an endeavor often represents several years of work by the individual, and an institution may have expended thousands of dollars in giving that person an opportunity to carry out the research. And yet it is pathetic to see the results embodied in an inarticulate exposition. That young investigators are not being given guidance is manifested by the appeal made by the editors of the *Journal of Clinical Investigation* in the issue for September, 1948, when they cited the deficiencies of papers being submitted to them and asked that more diligence and care be given to the preparation of a manuscript. Some principal investigators are so engrossed with their own research and personal interests that they have neither the time nor the concern for aiding the young investigator in the assimilation of his data and preparing them for publication. The writing of a scientific paper is not easy, and there are no short cuts in preparing an accurate and readable report.

The Clinical Investigator and His Economic Status

Individuals who elect to spend three or more years as a resident in one of the clinical disciplines face the grim reality that the financial return at best is but sufficient to meet the basic needs of existence. It is to be regretted that this applies to those who are encouraged to extend this postgraduate period of training and continue on with clinical investigation. Considerable admiration

must be extended to the courage of the war veteran with a wife and children who has made the decision to stay with clinical research. Too often, able individuals find it utterly impossible to continue on with the stipends accorded them, and they drop out and go into more lucrative fields of medical endeavor, especially private practice. It has become quite obvious that medical schools, hospitals, and institutes of research cannot satisfactorily finance the medical program of graduate training in medicine. It is also apparent that private enterprise in general cannot continue to support medical research as in the past. Where, then, are the institutions charged with the responsibility of training clinical investigators to turn for financial aid? Major support today is coming from the Federal Government. The taxpayer is footing large expenditures of funds for medical education and research. Because of this postwar development, I would like to discuss briefly Federal aid that is coming from three sources. First, a most remarkable union has been made between medical education and the Veterans Administration. This joint enterprise has resulted in an excellent training program for residents in the various specialties, and it has encouraged sound clinical investigation. The end result has not only been of considerable aid to the medical schools in discharging their obligations for postgraduate medical training to the veterans, but the patients have benefited from the skilled medical care. If a large segment of clinical material is to be hospitalized under the Veterans Administration in the future as at the present time, it is absolutely essential that medical schools continue with this cooperative effort. But the union will only continue successfully if the same high standards set up by the Deans' Committees and the Veterans Administration continue in force. A second type of Federal aid to medical education and research is that manifested by the United States Public Health Service. These funds have been administered wisely and have supported many excellent research projects. In addition, the Public Health Service has fostered a modest but sound program of education and research for promising young individuals. A third type of Federal aid to education and research is that distributed by the military branches. It seems almost incredible that in a free society desperately seeking ways to achieve world peace, tremendous sums of money should be allocated to military agencies for applied and fundamental research, particularly when much of the research has no direct bearing on military activities. While freedom of thought and action in research has accompanied the Army and Navy grants for medical investigations, it should never be forgotten that anything earmarked military implies security and that, under these circumstances, freedom may be stifled overnight in the interests of "national security."

Some young investigators are sorely grieved, and perhaps rightly so, at the scanty financial returns afforded them during their formative years. If these individuals anticipate later on in life an income commensurate with their labor and contributions to medical research, they will be sadly disappointed. As the young investigator matures, and after he has established his ability as a

clinician and as a scientist, he is often faced with the serious decision as to whether he can continue in the field of medical research on a full-time basis. Too many times, economic circumstances demand that he compromise and attempt the blending of the private practice of medicine with clinical research. It is not my purpose to belabor the question of private practice versus the full-time clinical investigator, but this problem confronts most men who are attempting to develop and direct medical research. As he concluded his address to the first meeting of this Society, Dr. Meltzer stated, "Teaching medicine and furthering its science is a very serious business which ought to be carried on by men who are ready to devote all or most of their time to it—but let me tell you: beware of practice. It is a bewitching graveyard in which many a brain has been buried alive with no other compensation than a gilded tombstone." Twenty years later, another great figure in clinical research, Sir Thomas Lewis, wrote, "No investigator can be successful who allows, or is forced by circumstances to allow, solicitude for his patients to preoccupy his mind." While it would be highly desirable today for competent young men to continue on a full-time basis, we cannot escape the bald fact that hospitals and medical schools are able to support in this manner but a very limited number of these individuals. I am of the opinion that a man can carry on a restricted private practice and engage in clinical research. Under these conditions, a clinician is often a better teacher and, if clinical investigation means the study of human disease, patients coming to him for advice may be of considerable aid in the resolving of a clinical problem. But unfortunately, the well-trained clinician possessed of desirable personal characteristics is often sought after by other physicians and patients to the detriment of his research. A soaring income accompanied by an elevated social position frequently has more enchantment than the self-sacrifice and many frustrations that go with clinical research.

The Clinical Investigator and His Obligation to Society

The era in which we are living has been called the Scientific Age, and now we are told about the coming Atomic Age. Society with its "cold wars" and anxious tensions expects and needs leadership from scientists. While the attention of the public is centered chiefly on

those working in the fields of nuclear physics and electronics, the medical scientist has also grown in stature. Is the medical man prepared to assume his responsibility of leadership? One of the undesirable aspects of medical education is the emphasis placed upon the natural sciences and the scant attention given to the study of history, political economy, and the social sciences. When the student of medicine in this country finishes his undergraduate and postgraduate education, he has received the finest technologic training available in the world today. But he has not been educated for a position of leadership in society at large. He does not know, nor often does he appear to care, about the social, political, and economic changes disturbing the equilibrium of society. In his zeal to unravel a mystery of pathologic physiology at the bedside or in the laboratory, he has no time for the problems of the world with its clashing ideologies, opposing cultures, social hatreds, and nationalistic pride masking economic greed. The medical school curriculum could stand a little more emphasis upon social pathology, even at the expense of morbid anatomy. The young clinical investigator is the leader of medical education tomorrow. In concluding my remarks this morning, I would like to plead that the young medical scientists do not hide within their ivory towers of learning, oblivious of the community and its problems. As the investigator pursues his training, let him give time and thought to the immediate issues facing mankind. As he attempts to mold and influence the thinking and attitudes of medical students under him, let him remind his charges that the possessor of a medical degree is a humanitarian rather than merely a doctor dispensing his technologic skill to the highest bidder. Let him instill within his students the desire to acquire a social conscience. Let the young instructor inculcate upon his classes the fact that environmental factors are often more important in the genesis of human illness than organic changes. Finally, he knows and his students know that the distribution of medical care will undergo some changes. Let him beseech his students as they attempt to resolve this problem in their own minds that they utilize the experimental method in which conclusions are reached only after accurate data have been assimilated rather than on the basis of ignorance and selfishness.

ABSTRACTS

Value of Blood and Urine Lactate Response to Physical Effort as an Index of Physical Fitness. DAVID I. ABRAMSON, and (by invitation) ROBERT W. KEETON, WARREN H. COLE, H. H. MITCHELL, J. M. DYNIEWICZ, M. C. GEPHARDT, S. J. PRESLEY, and W. R. KEARNEY, Chicago, Ill.

The effects of various work loads on the lactic acid in the blood and urine were studied in a group of patients in widely different states of physical fitness as judged by clinical standards. When all were subjected to the same small amount of work on a treadmill, the individuals in good physical condition showed much less of an increase in the blood lactate level, with the peak of the curve appearing sooner, than was observed in those in poor shape. The patients falling in categories between the two extremes demonstrated changes which could be correlated with their relative states of physical fitness. From the alterations noted in urine lactate content, the patients could only grossly be divided into good or poor performers.

When the individuals walked on the treadmill almost to the point of exhaustion, the variations in blood lactate response were such that further subdivisions with regard to gradations in physical fitness were made possible. In the patient in excellent shape, the blood lactate curve showed a peak, occurring at a relatively low point, early in the exercise and then a fall during the remainder of the walk; this continued into the post-exercise period. The individual in the next lower category did not demonstrate the fall during the latter part of exercise but a plateau instead. The patient in poor physical shape showed an ascending slope during exercise and a peak, occurring at a much higher level, late in the post-exercise period.

Following a major surgical procedure and its associated period of physical inactivity, many of the patients demonstrated alterations in the blood lactate curve which were interpreted as a decrement in the efficiency of their reaction to the work load.

It is concluded that the blood lactate response to exercise is a sensitive index of physical fitness.

Genetic Studies of 201 Persons with Hereditary Hypercholesterolemia (Thirty-five Families and Twenty-nine Individuals). DAVID ADLERSBERG and ALBERT D. PARETS (Introduced by Ernest P. Boas), New York, N. Y.

Continuing previous studies, 35 families (172 members) and 29 individual patients with hereditary hypercholesterolemia (Familial Xanthomatosis), totalling 201 persons, were investigated. Forty-nine patients (24 per cent) exhibited the full syndrome of hypercholesterolemia, coronary artery disease and one or more of the following: xanthoma tuberosum or tendinosum, xanthelasma and juvenile or senile corneal arcus; 122 had hypercholesterolemia (300 mg. per cent or more); 61 exhibited xanthelasma; 25 ex-

hibited xanthoma and 35, corneal arcus. Coronary artery disease was present in 80 patients (40 per cent). Among these, serum cholesterol was determined in 66 and was found elevated above 300 mg. per cent in 57. Thus, the two most frequent abnormalities encountered in these xanthoma families were hypercholesterolemia and coronary atherosclerosis. Xanthelasma and arcus were next in frequency, while xanthoma was found least often. Genetic analysis revealed that the inborn error of cholesterol metabolism was inherited as an incomplete dominant trait. The significance of these findings in the etiology of coronary artery disease is discussed.

The Role of Phospholipids in High-Lipid Sera in Cirrhosis and Nephrosis. EDWARD H. AHRENS, JR., and HENRY G. KUNKEL (Introduced by Sidney Rothbard), New York, N. Y.

In a large series of lipemic (milky) sera from 15 patients with nephrosis and non-lipemic high-lipid sera from 20 patients with biliary cirrhosis the ratio of phospholipids to total lipids (PL/TL) was found to be high in non-lipemic sera and low in lipemic sera. In fasting sera with total lipids ranging from 600 to 2,900 mg. per cent, PL/TL in non-lipemic sera was 0.29 or higher in 22 of 24 instances, whereas in lipemic sera PL/TL was 0.25 or lower in 15 of 19 instances. These data suggest that the clarity of high-lipid sera in biliary cirrhosis is explained by the characteristically large proportion of phospholipids, since these lipids are markedly hydrophilic by nature of their water-soluble side-chains. By this concept lipemia is due to a low proportion of hydrophilic lipids rather than, as commonly postulated, to an absolute increase of neutral fat.

This hypothesis was tested by destroying lecithin and sphingomyelin of serum enzymatically, using *C. welchii* lecithinase which splits phosphorylcholine from lecithin and sphingomyelin, depriving these lipids of their hydrophilic side-chains and leaving water-soluble diglycerides. Exposure of normal and high-lipid sera to this enzyme produced a lipemia indistinguishable grossly and microscopically from that of nephrosis, and the degree of turbidity measured spectrophotometrically was linearly proportional to the total lipid content.

Further studies showed that under certain conditions measurable enzymatic hydrolysis of serum phospholipids occurred before turbidity appeared or increased. Thus, it was demonstrated in high-lipid sera of nephrosis as well as cirrhosis that phospholipids exert an appreciable solubilizing effect upon grossly elevated hydrophobic lipids.

These data have possible application in studies of fat transport and deposition of fat in tissues.

A New Theory of Blood Coagulation with Particular Reference to the Role of Prothrombin in Coagulation.

tors. BENJAMIN ALEXANDER and (by invitation), GRETA LANDWEHR and ROBERT GOLDSTEIN, Boston, Mass.

Serum contains a substance which, arising during coagulation, can accelerate the conversion of prothrombin in plasma to thrombin by thromboplastin plus calcium. Many of its properties have been delineated, and it has been separated in a fraction comprising 20 mgm. of protein from 100 cc. of serum. Evidence indicates that it is a new clotting factor, distinct from Ac-globulin of Ware and Seegers, Factors V and VI of Owren, or Labile Factor of Quick.

The amount of accelerator which evolves during coagulation is related to the amount of prothrombin consumed. In hypoprothrombinemia—congenital, dicumarol induced, or resulting from liver disease—abnormally small amounts of accelerator are elaborated. Furthermore, the interaction of purified prothrombin preparations with thromboplastin and calcium yields substantial amounts of accelerator in addition to thrombin. Accordingly, it is proposed that prothrombin (M.W. 140,000) may be split during its conversion to give thrombin (M.W. 70,000) and the accelerator. This concept is suggested also by remarkable similarity in some respects between prothrombin and the accelerator.

The agent cannot accelerate prothrombin conversion in the absence of a non-prothrombin factor present in fresh plasma. Also, a short interval (approximately 2 minutes) is required for these components to interact. The plasma moiety is labile and appears identical with Labile Factor, Factor V and Plasma Ac-globulin, all of which, it is generally agreed, are probably the same.

On the basis of the above a new theory of blood coagulation is proposed: in the presence of thromboplastin and ionized calcium the prothrombin and serum is slowly cleaved to yield thrombin and serum accelerator. Under the influence of the serum accelerator plasma Ac-globulin (Factor V, Labile Factor) is converted to serum Ac-globulin which then accelerates the conversion of additional prothrombin to thrombin and more serum accelerator.

The overall reaction thus proceeds with ever increasing velocity until the prothrombin is almost entirely consumed. Reduction in serum accelerator after dicumarol administration rather than the hypoprothrombinemia per se may explain the efficacy of this drug in the prevention and treatment of thromboembolic disease.

Renal Function in Multiple Myeloma. JOHN B. ARMSTRONG (Introduced by Jerome Harris), Durham, N. C.

Patients with multiple myeloma frequently die in uremia. Pathological examination has emphasized blockage of the renal tubules by protein casts, as the cause of the renal failure. If this were true, functional tests should show approximately equal decrease in glomerular and tubular function.

Eight patients with a clinical diagnosis of multiple myeloma, confirmed by x-ray, bone biopsy, and other exami-

nations, were selected who showed no evidence of other kidney disease. All patients had normal blood pressures and NPN concentrations. The glomerular filtration rate (C_{IN}), effective renal plasma flow (C_{PAH}), and tubular secretory maximum (T_{MPAH}) were determined, each value being an average of two or more urine collection periods.

In each instance, all three functions were depressed to a lesser or greater degree. In three patients the tubular secretory maximum was much better preserved than glomerular filtration. The severity of renal impairment did not seem to correlate with the hematologic or serum protein abnormality, nor with the amount or duration of Bence Jones proteinuria. The renal functional impairment resulting from hemoglobin- and myoglobin-uria, studied experimentally by Corcoran and Page, showed greatly depressed tubular maxima, compared to the other renal functions, whereas in these patients the converse was the rule.

Tubular obstruction by precipitated protein does not adequately explain the renal impairment frequently found in patients with multiple myeloma. The pathological findings often show relatively little blockage. In one patient who died suddenly without uremia or dehydration, few casts were seen. It seems likely that cast formation may be part of the terminal picture of this disease and not the fundamental basis of the renal failure.

A Comparative Study of the Effects of Tetraethylammonium Chloride and Veratrum Viride on Blood Pressure of Normal and Toxemic Pregnancies. N. S. Assali and Albert A. Brust (Introduced by Eugene B. Ferris), Cincinnati, Ohio.

Humoral maintenance of toxemic hypertension as contrasted with largely neurogenic blood pressure control at term of normal pregnancy has been suggested by observations after autonomic blockade with tetraethylammonium chloride (TEAC). Application of this concept has been further investigated in the present study in which veratrum viride, frequently used in the treatment of toxemia, has been subjected to physiologic evaluation. Ten normal term pregnancies and 12 toxemic pregnancies have been studied with blood pressure assay using intravenous TEAC and veratrum.

Negligible blood pressure response to veratrum occurred at term and postpartum of normal pregnancy, whereas TEAC invariably produced marked blood pressure fall prepartum and minimal responses after delivery.

In toxemia, veratrum lowered systolic and diastolic levels by 50 per cent of the total blood pressure. TEAC administration to the same patients reduced the blood pressure by only 10 per cent. With postpartum recovery from toxemia the marked veratrum response disappeared. As veratrum blood pressure floors rose to levels comparable to those observed postpartum of normal pregnancy, the TEAC floors descended to the same range.

Veratrum side effects (bradycardia, epigastric burning, nausea and vomiting) occurred regularly, but the magnitude of the depressor response was independent of these vagal stimulation components of the drug action. Administration of TEAC at the height of veratrum action in-

variably abolished the side effects, yet the depressor action persisted.

The data: (1) Demonstrate diametrically opposing blood pressure effects of TEAC and veratrum in both normal pregnancy and toxemia. (2) Eliminate vagal stimulation as the cause of the marked depressor responses to veratrum in toxemia. (3) Indicate that the blood pressure of the toxemic hypertensive is consistently sensitive to veratrum. (4) Offer clues for discussion of possible modes of mediation of veratrum depressor responses in toxemia.

The Problem of Infection of Man with the Virus of Newcastle Disease of Chickens. F. B. BANG and DAVID T. KARZON (Introduced by Joseph L. Lilienthal Jr.), Baltimore, Md.

From two of three cases of acute conjunctivitis occurring in laboratory personnel working with the virus of Newcastle disease, we have isolated this virus on two occasions each. These individuals did not develop a high titer of neutralizing substance in their fresh sera. In a survey of eight other persons exposed in the laboratory but who had not had conjunctivitis, one was found whose fresh serum neutralizes more than one million lethal infectious doses for the chick embryo. After heating to 56° C. for one-half hour, this serum loses a large part of its activity, neutralizing less than one thousand lethal doses. When the serum is diluted, there is a very rapid drop in its titer of neutralizing substance. This appears to stand in contrast to a slower fall in titer when the immune serum of chickens convalescent from experimental Newcastle disease is similarly diluted. The substance has been consistently present in fresh samples of serum taken from this person during the past year. No substance of comparable activity has been found in the other sera tested. The nature of the heat labile component is under study.

A Quantitative Analysis of the Effects of Adrenocorticotrophic Hormone (ACTH) on Potassium (K) and Phosphorus (P) Metabolism. FREDERIC C. BARTTER, PAUL FOURMAN, ANNE P. FORBES, WILLIAM M. JEFFRIES and ELEANOR DEMPSEY (Introduced by Fuller Albright), Boston, Mass.

In man, ACTH affects K and P metabolism each by three established mechanisms. For K they are: (1) the loss of protoplasm, (2) the retention of extracellular fluid (e.c.f.), and (3) the specific effect of adrenal "salt" hormone in causing K loss. For P they are: (1) the loss of protoplasm, (2) the retention of e.c.f., and (3) the loss of bone (osteoporosis).

Balance studies with ACTH are reported. "Corrections" are applied to the K and P excretions for protoplasm, e.c.f., and bone changes. A fourth effect of ACTH on K and P is thereby unmasked, namely, K and P retention "on" ACTH, and K and P loss "off" ACTH. The deviations of K and P so revealed are highly correlated. This fourth mechanism affects K in the opposite direction to that of the "salt" hormone, and is not elicited by desoxycorticosterone alone.

We infer that this fourth effect represents passage of K and P into and out of cells, possibly associated with glycogenesis and glycogenolysis, respectively. We suggest that the K and P liberated when protoplasm is broken down are retained with glycogen. The net result is a transformation of protein energy to the more readily available glycogen energy.

Apparent Role of Shock in Production of Renal Damage Accompanying Hepatic Injury. JAMES H. BAXTER (Introduced by Benjamin M. Baker, Jr.), Baltimore, Md.

Rats fed diets containing pyridine regularly developed acute hepatic necrosis; the animals which survived long enough developed cirrhosis. Before death, the animals usually appeared pale and were cold to the touch. The livers of animals autopsied in the terminal stages of necrosis were engorged with dark blood. There was marked obstruction to perfusion of fluid through the livers. Bleeding from the rectum sometimes occurred. Disturbances of hepatorenal vasotropic factors (Shorr), in addition to obstruction and trapping of blood in the liver, may have contributed to the production of shock.

Many of the rats fed pyridine also developed renal injury. Degenerative changes and sometimes necrosis occurred in the convoluted tubules. Regenerative changes followed, with the formation of cellular buds or masses in the region of the straight segments. Generalized or localized dilatation of tubules with flattening of epithelium was regularly observed, and areas of cortical scarring and atrophy resulted when length of survival permitted.

Liver injury frequently occurred in animals without kidney injury. However, kidney injury was seldom observed prior to the occurrence of extensive liver injury, even though some animals remained on the diets for weeks without developing liver injury. Furthermore, the most extensive renal injury occurred in animals which remained in shock for considerable periods or which survived recurrent episodes of shock. It appeared likely that the renal injury was at least in part due to shock, resulting in impairment of cortical circulation with anoxia of tubular cells, oliguria, and increased concentrations of protein in the urine. Similar mechanisms may participate in the production of renal injury under a wide variety of circumstances.

Preliminary Studies on an Indirect Method for Determining Portal Pressures. WILLIAM B. BEAN and (by invitation) WILLIAM D. PAUL and MURRAY FRANKLIN, Iowa City, Iowa.

There are circumstances in which it is desirable to know whether or not pressure in the portal vein is elevated. Previous observations on portal pressures have been confined to experimental animals except for a few direct measurements obtained during abdominal operations. We have approached the problem in normal persons and those with clinical signs of cirrhosis of the liver by observing through the proctoscope or sigmoidoscope changes in color of the mucosal surfaces with measured increments of intra-luminal pressure.

The escape of air upwards in the colon is prevented by inserting an inflatable rubber bag attached to a tube. The sigmoidoscope is connected with a water manometer and by T-tube to a rubber bulb pump and small air reservoir so that air pressure within the rectum and sigmoid can be varied at will and measured readily. Subjects are prepared by cleansing enemas. The rubber bag is inserted, the proctoscope introduced and the bag is inflated. The glass window with adaptor for communicating with the manometer and pressure reservoir are adjusted. With the patient in the left lateral (Sim's) position, the anatomical center of the liver is approximately on the same level as the observed mucosa. Pressure must be increased slowly to reduce intestinal movements and cramps. At levels between 10 and 20 cm. of water, the pink color fades and many vessels are seen against the pale background. Between 40 and 60 cm. the caliber of the vessels narrows. With manual pressure over the liver, the level at which blanching occurs is elevated to 30 cm. or more. Similar levels have been noted in persons with portal hypertension and cirrhosis. The method may be useful in evaluating pain thresholds in the lower bowel and the acute effects of drugs.

Myofilaments and Myofibrils of Cardiac Muscle. H. STANLEY BENNETT, Seattle, Wash.

Electron micrographs have been obtained of frog cardiac muscle elements fixed in formaldehyde or trichloroacetic acid and fragmented with blender and homogenizer. The preparations have yielded pictures of myofibrils, which prove to be packed with parallel myofilaments similar to those found in striated skeletal myofibrils by Hall, Jakus, and Schlmitt. The cardiac muscle myofilaments are slightly thicker than those of skeletal muscle, averaging 240-260 Å in diameter, and show an axial repeating period of about 400 Å when unstretched. As in skeletal muscle, the filaments appear to be indefinitely long, extending through many sarcomeres. Evidence of fine structure within the 400 Å period can be seen, but the material does not permit definitive analysis of such details. The filaments are capable of being stretched readily and fortuitously during fragmentation or on the supporting film, so that periodicities from 375 Å to about 750 Å may be measured, depending on the degree of stretching. Electron micrographs of cardiac muscle myofibrils show the various bands visible with the light microscope, but the bands are less distinct than in skeletal muscle. The Z-band is about 0.15 μ wide in cardiac muscle.

The Effect of a Cation Exchange Resin on Electrolyte Balance and Its Use in Edematous States. EUGENE Y. BERGER, LESLIE IRWIN, BENJAMIN ROSENBERG and ROSLYN JACKENTHAL (Introduced by Alfred E. Cohn), New York, N. Y.

An exchange resin, Liquonex CRW, which removes cations from solution in exchange for hydrogen was fed to a subject on a constant diet. An electrolyte balance study was conducted for three weeks before, five weeks during, and three weeks following the administration of the resin. Approximately 80 per cent of dietary sodium and 70 per

cent of dietary potassium appeared in the stool. There was no evidence of a calcium deficiency. A compensated acidosis was induced by the liberation of hydrogen ions in exchange for sodium ions. The excess chloride, phosphate, and sulphate anions were balanced in the kidneys by formation of ammonia.

Fixation of sodium in the gut is equivalent to restricting sodium in the diet; hydrogen ion release is the equivalent of giving ammonium chloride or an acid ash diet. Both of these procedures are commonly used to help prevent edema formation. Therefore, two patients suffering from heart failure and edema and one from cirrhosis of the liver and ascites were fed the resin. In the two cases of congestive heart failure on a diet containing 6 grams of salt daily, the use of resin replaced the need for mercurial diuretics and salt restriction. In the patient with cirrhosis of the liver on a similar diet, the ascitic fluid disappeared in 22 days without the use of mercurial diuretics. A well marked but still compensated acidosis was produced in the normal individual and in the patient suffering from cirrhosis of the liver. These observations indicate that a cation exchange resin can restrict the absorption of sodium from the intestine. Use of the resin may therefore become important whenever it is desirable to maintain a high protein low sodium diet.

Studies in the Renal Mechanisms for the Excretion of Potassium. ROBERT W. BERLINER, THOMAS J. KENNEDY, JR. and JAMES G. HILTON (Introduced by A. B. Gutman), New York, N. Y.

When large amounts of potassium salts are administered to normal dogs by constant intravenous infusion, the amount excreted in the urine may exceed that filtered by as much as 80 per cent. Exact reproduction of such experiments is mechanically difficult in humans, but potassium clearances greater than glomerular filtration rate have been observed in normal man, and in normal and hypertensive man on the rice diet.

The coexistence of a secretory mechanism for excretion of a substance ordinarily filtered and reabsorbed has not previously been observed. The paradoxical behavior of K^+ , capable of moving across the tubular epithelium in opposite directions, makes evaluation of the relative magnitude of the reabsorptive and secretory mechanisms difficult since only the resultant can be examined. Efforts to evaluate the roles of these two opposing mechanisms have been made chiefly in dogs.

Chronic administration of moderate doses of potassium by inducing tolerance, facilitates excretion of sudden large loads of this ion at more rapid rates and at lower plasma concentrations than in unprepared dogs.

Infusion of potassium with non-reabsorbable anions such as ferrocyanide or thiosulfate regularly results in ratios of excreted to filtered higher than with reabsorbable chloride. Moreover, in such experiments, the minimal secreted potassium is so much larger than the anions which could possibly have been secreted that cation exchange must have occurred. Hypothetical mechanisms, the overall result of which is ionic exchange, are discussed.

When infused sodium thiosulfate or ferrocyanide is progressively replaced by the corresponding potassium salt, change from net reabsorption to net secretion of potassium is first associated with increased excretion of chloride and bicarbonate, and, later, reduced excretion of sodium. This probably indicates that excretion of large amounts of potassium is initiated by depression of reabsorption and enhanced by cation exchange.

Studies in Hypothermia: Part I—Oxygen Consumption, Transport and Utilization in Dogs at Low Body Temperature. W. G. BIGELOW, W. K. LINDSAY, R. C. HARRISON, R. A. GORDON and W. F. GREENWOOD (Introduced by James A. Dauphinee), Toronto, Canada.

This is the report of the first of a series of studies dealing with the physiological effects produced in dogs by general hypothermia.

Twenty-seven mongrel dogs were cooled to body temperatures of 20° C. or lower, by being placed in a controlled temperature room at -10° C. Oxygen consumption was determined in the first experiments by analysis of expired air collected in a Douglas bag and in the later ones by the use of a modified Tissot spirometer. Arterial and venous oxygen saturations and carbon dioxide contents were measured at intervals. The dogs were revived by placing them in a water bath at 42° C.

One hundred and twenty valid determinations of oxygen consumption during the process of cooling and rewarming are reported. Early in the study it was found essential to eliminate all shivering and to maintain normal arterial oxygen consumption. Anesthesia was used to accomplish the former, artificial respiration the latter. Oxygen consumption was found to decrease steadily and in a relatively constant manner at the rate of 5 per cent per degree Centigrade of temperature lowering, and to increase at a similar rate during rewarming.

The determination of arterio-venous oxygen differences revealed that, at least down to 18° C. and in the presence of a satisfactory heart action, the circulation in these cooled dogs was adequate to transport oxygen to the tissues.

The finding that the increase of oxygen consumption on rewarming paralleled the decrease on cooling, together with the fact that the general deportment and response of the dogs that survived showed no evidence of tissue hypoxia, indicates that tissues in the cold state are capable of oxygen utilization.

Generalized hypothermia under the conditions of this study reduces tissue oxygen consumption without producing significant tissue hypoxia.

Coronary Blood Flow, Cardiac Oxygen Consumption and Efficiency in Man. R. J. BING, M. HAMMOND, J. HANDELSMAN, S. R. POWERS, F. SPENCER, J. ECKENHOFF, W. GOODALE, J. HAFKENSCHIEL and S. KETY (Introduced by Alfred Blalock), Baltimore, Md. and Philadelphia, Pa.

The coronary blood flow and oxygen consumption per 100 grams of left ventricular tissue have been studied in

30 individuals, by combining the nitrous oxide method with coronary sinus catheterization. Left ventricular efficiency was calculated for normal heart muscle. In hypertrophy, only low values for efficiency can be considered significant, since total left ventricular weight cannot be estimated. Tests were performed on normal individuals, and on patients with anemia, essential hypertension and coarctation. Four patients in failure were also studied.

In the normal, left ventricular flow averaged 65 cc./100 grams/minute, left ventricular oxygen extraction 12 vols. per cent and left ventricular oxygen consumption 7.8 cc./100 grams/minute. The normal left ventricular efficiency averaged 23 per cent. In anemia, the coronary flow was increased, left ventricular extraction and oxygen consumption/100 grams/minute were reduced. In essential hypertension coronary flow/100 grams/minute, left ventricular oxygen extraction and oxygen consumption/100 grams were normal. In coarctation coronary flow/100 grams/minute, AV difference and oxygen consumption/100 grams/minute were increased. In failure the coronary flow/100 grams/minute was reduced and the oxygen extraction slightly increased. The oxygen consumption/100 grams/minute was normal. These findings indicate that 1, chronic increase in load results in no change in oxygen consumption per unit weight but in a total increase in oxygen consumption due to hypertrophy. 2, The cardiac efficiency in failure is low.

Characteristics of Visceral Sensation in Man, as Observed in Normal Subjects and Patients with Unilateral Sympathectomy. J. R. BINGHAM (by invitation), F. J. INGELFINGER and (by invitation) R. H. SMITHWICK, Boston, Mass.

Deep somatic pain in man can be differentiated from abdominal visceral pain. In 5 subjects, deep somatic pain was produced by injecting the intraspinal ligaments and the rectus abdominis with hypertonic saline. Before, during, and after deep somatic pain so produced, a balloon was distended in various parts of the duodenum and jejunum. The two types of pain were perceived to be clearly different. These observations do not support the statement of Lewis that deep somatic and abdominal visceral pain are identical.

After unilateral sympathectomy, pain produced by distending the gut is referred to the unoperated side. This observation was unequivocal in the 10 patients studied. The degree of lateralization appeared to vary with the site of stimulation. Greatest lateralization occurred with duodenal or biliary tract pain, less with high jejunal, and least with low jejunal or high ileal pain. This observation may explain the contradictory findings of others.

After unilateral sympathectomy, the pain threshold is elevated. In 4 patients (2 subjected to intestinal, and 2 to biliary tract distention), almost double the amount of pain stimulus was required after, as was needed before sympathectomy. In 5 other patients, studied only post-operatively, the pain threshold was elevated as compared with the normal average. This observation may explain why unilateral sympathectomy sometimes relieves visceral pain arising from a bilaterally innervated organ.

The common duct is bilaterally innervated. Distention of the common duct produced pain in one patient with a right unilateral, and in one patient with a left unilateral sympathectomy. This observation, confirming Ray's, emphasizes that complete desensitization of the biliary tract cannot be achieved by right sympathectomy.

Metabolic Fate of Infused Erythrocytes in Man. F. ROSS BIRKILL, MARY A. MALONEY and STANLEY M. LEVENSON (Introduced by John B. Youmans), Chicago, Ill.

The metabolic fate of infused erythrocytes in adults made significantly polycythemic by transfusions has not been known. Only inadequate and incomplete information has been available on erythrocyte survival and bone marrow function in such individuals. Data on these points were obtained in two normal adult males on a constant diet receiving serologically indentifiable, fresh, separated erythrocytes. Observations were made on body weight, nitrogen, potassium, and phosphorus balances; circulating plasma protein and erythrocyte mass; erythrocyte survival; sternal bone marrow; reticulocyte counts; serum bilirubin concentration; urobilinogen excretion; and liver function.

Survival time of the infused erythrocytes was not shortened. The infused red cell mass decreased at a normal, expected rate of 0.8 per cent per day. Concomitantly, the mass of the recipient's own erythrocytes declined at a rate of 0.4 to 0.8 per cent per day in direct proportion to the amount of the infusions. This progressive fall in the subject's own erythrocyte mass was probably due to erythropoietic depression rather than to abnormally increased destruction. This is suggested by the normal survival of the infused erythrocytes and by urobilinogen excretion consistent with breakdown of the total red cell mass at a normal, not an increased, rate. There was a direct linear relationship between the extent of bone marrow depression and the degree of induced polycythemia.

A slow, steady excretion of 0.5 to 1.0 grams of nitrogen per day (above the control equilibrium value) began shortly after the infusions and continued for one month. The total extra nitrogen excreted was roughly equal to the total nitrogen content of the infused erythrocytes. However, this excess nitrogen derived only in small part from the infused red cells. The greater part could be accounted for almost completely by nitrogen diverted from normal erythrocyte synthesis as a result of marrow depression.

The Effect of Increased Intra-Abdominal Pressure Upon Renal Excretion of Water, Sodium and Potassium in Normal Human Subjects and in Patients with Diabetes Insipidus. S. E. BRADLEY, and (by invitation) G. H. MUDGE, W. D. BLAKE and P. ALPHONSE, New York, N. Y.

Elevation of intra-abdominal pressure in man by application of a pneumatic girdle under a pressure of 80 mm. Hg has been shown to depress glomerular filtration, renal blood flow, and maximal tubular glucose reabsorption and diodrast excretion. The output of urine is greatly reduced and the urinary concentrations of such substances

as mannitol and inulin increase. Further studies were undertaken to assess the role of the antidiuretic hormone of the pituitary in this phenomenon and to determine whether electrolyte retention also occurred.

Mannitol, p-aminohippurate (PAH), sodium, and potassium clearances were determined simultaneously in six normal human subjects and in five patients with uncontrolled diabetes insipidus before, during, and after abdominal compression. In all but in two normal subjects and one patient with diabetes insipidus, glomerular filtration (as mannitol clearance) and renal blood flow (PAH clearance) decreased significantly, and the excretion of sodium, potassium, and water was regularly reduced. These responses were identical in both groups of subjects. Sodium and water output usually fell more than filtration, whereas changes in potassium excretion appeared to parallel changes in filtration. In most instances, the urinary concentration of sodium decreased during compression. All values tended to return toward the control levels following release of pressure. Increased intra-abdominal pressure appears to induce a renal retention of water and electrolytes primarily as a result of a reduction in glomerular filtration, independently of the production of antidiuretic hormone. Augmented tubular re-absorption of water and sodium may account for disparities between changes in filtration and in sodium and water excretion observed in some subjects.

Tetralogy of Anomalous Pulmonary Drainage, Auricular Septal Defect, Right Ventricular Hypertrophy and Patent Ductus Arteriosus. ROBERT A. BRUCE, FRANK W. LOVEJOY, EARLE B. MAHONEY, GEORGE B. BROTHERS, PAUL N. G. YU and RAYMOND PEARSON (Introduced by Nolan L. Kaltreider), Rochester, N. Y.

Since patent ductus arteriosus is usually amenable to surgery, and ligation of an anomalous pulmonary vein has been recommended, the combination of both lesions together with auricular septal defect and right ventricular hypertrophy presents a complicated clinical problem. Two out of 12 possible patients reported in the literature lived for 19 and 27 years. We have studied 2 cyanotic young women, one of whom was proved to have this tetralogy at autopsy, and the other had similar findings by catheterization. The first had frequent major hemoptyses for which she was subjected to ligation of an anomalous right pulmonary vein demonstrated by catheterization. She died of pulmonary edema, immediately following ligation of the anomalous vein. The second had marked clubbing but no hemoptyses. The x-ray findings in both were a relatively small heart despite enlargement of the right auricle and prominence of the pulmonary conus and of vascular markings in the lungs. Each had right axis deviation electrocardiographically. Exercise studies showed transient paradoxical response in the respiratory efficiency attributed to the shunts. The right ventricular pressure considerably exceeded the systemic pressure in both patients, and in one catheterization of the left ventricle demonstrated that the duration of systole was less than that of either the right ventricle or systemic pulse. This was in accord with Brody's hypothesis that the right ventricle

could supply a major part of the systemic circulation through the ductus. Our experience shows that cyanosis contra-indicates ligation of an anomalous pulmonary vein whenever it is demonstrated to be draining into the right heart and that in this tetralogy patency of the ductus is essential. Slides of the laboratory data, anatomical findings in the first patient, and cinefluorograms (courtesy of Dr. Sibley Watson) of both are shown to demonstrate this particular tetralogy of congenital cyanotic heart disease.

The Lack of Correlation between Glomerular Filtration Rate, and Serum Electrolyte Concentration Changes, Urinary Electrolyte Excretion, or Edema Formation Following Sodium Loads in Subjects with Normal Kidneys, Glomerulonephritis, and the Nephrotic Syndrome. CHARLES H. BURNETT, (by invitation) BELTON A. BURNOWS and (by invitation) ROBERT R. COMMONS, Boston, Mass.

The effects of sodium loads administered intravenously to subjects with normal renal function, and with glomerulonephritis in different stages were studied. Normal responses to 200 to 400 milliequivalents of sodium (as 0.5 M sodium bicarbonate) included: serum concentrations, sodium increased, potassium slightly but definitely decreased; urinary excretion, sodium and potassium increased; percentage excretion of filtered ion (calculated from C_{18}), sodium slightly and potassium markedly increased; ratio of reabsorbate concentration to serum concentration (R/S), sodium remained close to unity, potassium fell (as much as 25 per cent). The direction of these changes was consistent despite individual variations in filtration rate and urine flow.

A different sequence resulted in the nephrotic syndrome, with normal or only moderately low glomerular filtration rates; sodium rose or was unchanged in the serum, urinary excretion failed to increase, percentage excretion of filtrate remained low, but R_{Na}/S_{Na} was unchanged. Further edema always resulted. With one exception, the effects on potassium metabolism were identical with, or more marked than, those occurring in normals.

In glomerulonephritis, without edema or heart failure, both the normal and nephrotic responses occurred. Ability to excrete the sodium load diminished as C_{18} fell; but excess sodium was better excreted than in nephrosis, and edema never resulted. The potassium responses were accentuated in that percentage excretion of filtrate often exceeded 100 (suggesting renal tubular secretion of this ion).

It is concluded, that since the rate of sodium excretion could not be correlated uniformly with either the glomerular filtration rate or tubular reabsorption of sodium, the mechanism of edema formation remains undisclosed in the diseases studied. It is suggested that the almost invariable change in potassium metabolism resulting from sodium administration may represent an important factor in the maintenance of salt and water equilibrium.

The Incidence of Liver Involvement in Chronic Amoebiasis. RICHARD B. CAPPS and (by invitation) ALFRED BENNETT, Chicago, Ill.

The incidence of liver involvement in chronic amoebiasis is of interest both because of its bearing on treatment and also because of its role in the production of symptoms. In order to provide both a sensitive and a specific method of establishing the presence of amoebic hepatitis, the response to emetine of a group of liver function tests was studied. Observations were made on a series of 15 consecutive cases of chronic amoebiasis. All cases had symptoms but in no instance was fever present. Liver function tests including the cephalin cholesterol flocculation, thymol turbidity, serum alkaline phosphatase, serum bilirubin, bromsulphalein, 24 hour urine urobilinogen and urine coproporphyrin were performed before and after a course of emetine. In 11 cases the initial tests indicated mild liver dysfunction. Following emetine the abnormal findings returned to normal promptly or dropped sharply in almost all instances indicating a specific therapeutic response. In 10 of these 11 cases liver tenderness and symptoms consistent with hepatitis were present initially and also responded to emetine.

We believe that these findings indicate that a specific hepatitis is present in a large percentage of cases of chronic amoebiasis and is responsible for many of the symptoms. Unless other agents can be shown to be effective emetine should probably be used routinely in all cases of amoebiasis. Further studies are being conducted.

The Golgi Apparatus in the Cells of Synovial Tissue and Related Structures. PEDRO M. CATOGGIO and L. RAYMOND MORRISON (Introduced by Charles L. Short), Boston, Mass.

A study was made of the relationship between the size, configuration and localization of the Golgi element and the histological findings in tissue from joints, bursae and ganglia removed at operation from seventy-five patients. In some instances the relationship to the joint fluid was also studied.

The material was prepared according to the Da Fano technique. Tissue from some of the cases was also studied by other methods.

The clinical diagnoses were: normal joints, acute traumatic arthritis, chronic traumatic arthritis and degenerative joint disease, rheumatoid arthritis, miscellaneous joint disease, bursitis, ganglion.

Examination of the sections showed a well-developed Golgi element in the synovial cells. In some cases it was small, granular or simple and delicately looped and was often indifferently located within the cytoplasm of small cells; presumably in the "resting state." This appearance was usually associated with apparently normal synovial tissue. In other instances the Golgi apparatus was large, complex and lay in relation to the free border of the cell and was presumably "active." These specimens showed various synovial tissue alterations: increased number of synovial cells, larger cells, villi and often perivascular round-cell infiltration.

If increase in size and complexity of the Golgi apparatus is evidence of increased activity of the cells, the above findings suggest that the synovial cells in rheumatoid arthritis are often more active than in normal

joints. In degenerative joint disease the activity of these cells appears to be between that in rheumatoid arthritis and that in normal joints.

In the small number of joint fluids available, comparison of the fluid characteristics with the appearance of the Golgi element in the tissue cells does not provide adequate evidence to aid in determining whether or not synovial cells produce mucin.

Simultaneous Determination of Cardiac Output by the Acetylene and Direct Fick (Right Heart Catheterization) Procedures. CARLETON B. CHAPMAN, HENRY L. TAYLOR, CRAIG BORDEN, AUSTIN HENSCHEL, and ANCEL KEYS (by invitation) and RICHARD V. EBERT, Minneapolis, Minn.

Nineteen simultaneous measurements of the cardiac output by the acetylene and direct Fick (right heart catheterization) techniques were carried out on 7 normal subjects. The Grollman formula was used for acetylene determinations. The mean cardiac indexes were 2.47 ± 0.56 (acetylene), and 3.27 ± 0.78 (direct Fick) liters per square meter per minute. When plotted against each other, the results obtained by the 2 methods showed a definitely linear relationship ($r = 0.87$). Statistical analysis showed that the small deviation from a perfectly linear relationship was due to individual method errors. If the acetylene output (x) is known, the direct Fick output (y) can be calculated from the formula $y = 1.1682x + 0.7420$, the standard error of the estimate being ± 0.41 . The Grollman formula, therefore, can be made to yield results which closely approximate those obtained by the direct Fick procedure simply by altering the numerical constant.

In order to determine how much, if any, of the predictable difference between results of the 2 methods is due to recirculation of acetylene, 30 samples of pulmonary arterial blood were taken at from 9 to 55 seconds after acetylene entered the pulmonary alveoli. When the partial pressure of acetylene in the blood was plotted against time, recirculation began between 10 and 20 seconds after beginning of rebreathing and progressed in a linear fashion. For the interval between the first and second gas samples (9 to 19 seconds), the calculated mean partial pressure of acetylene in pulmonary arterial blood was 3.5 mm. Hg or about 5 per cent of the mean partial pressure of acetylene in the alveoli (61.5 mm. Hg). This confirms the view that such recirculation as occurs during the first 20 seconds after acetylene enters the alveoli is not enough seriously to affect the validity of the method.

Some Cardiac and Extracardiac Effects of Digitalis Glycosides. DON W. CHAPMAN and CARROLL A. HANDLEY (Introduced by James A. Greene), Houston, Texas.

Studies were undertaken to ascertain what relationship, if any, existed between the intravenous administration of digitalis glycosides and the serum concentrations of potassium and sodium and their effect on the electrocardiographic tracings; hematocrite; the plasma volume; and the extracellular fluid.

Digitoxin and digoxin were employed in concentrations from 0.1 to 0.2 mg./kg. body weight in twenty-seven dogs. Serial electrocardiograms were taken from lead 2 and blood samples were drawn at hourly intervals for the estimation of serum potassium and sodium. Sodium thiocyanate and T1824 were employed to ascertain changes in extracellular fluid and plasma volume at four to ten-hour intervals. Hematocrite determination was by the Wintrobe method.

When digitalis was administered in small doses so that relatively minor or no electrocardiographic effects were obtained, in general, there was but little change in the other studies. In larger doses an approximate qualitative relationship between the increasing height of the serum potassium and the electrocardiographic alterations, as seen in potassium intoxication, were noted. The initial changes observed were an increase in the amplitude of the T waves, followed by a decreased size of the R waves, and an increased amplitude of the S wave. In some, there was a disappearance of R waves with a depressed RST segment or a widening of the QRS complex. In others a partial or complete auricular arrest may have preceded the development of intraventricular block. Ectopic rhythms such as single or multiple premature ventricular contractions may be seen. However, in some instances, no direct correlation was noted with the height of the serum potassium. Marked increases in the hematocrite, a lowering of the plasma volume, and an increase in the extracellular fluid was observed when there were marked changes in the electrocardiographic tracings.

Multiple-Balloon-Kymographic Recording of Variations in Motility of the Upper Small Intestinal Tract in Man, Emphasizing the Need of Long Control Observations for the Adequate Evaluation of Drug Action. WILLIAM P. CHAPMAN, (by invitation) EIRWYN N. ROWLANDS, and CHESTER M. JONES, Boston, Mass.

Knowledge of spontaneous variations in intestinal motility in healthy subjects observed over long periods was regarded as essential for the evaluation of drugs, particularly when given orally. Fourteen studies averaging four hours in duration were made in twelve subjects, all except one being healthy young adults. Motility was recorded from the duodenum and upper jejunum using a four-lumen tube with balloons spaced at four-inch intervals. Placebos without verbal suggestion were administered on an average of fifty-one minutes after the start of the recording. Relative changes in contractions and "tone" or sustained tension of the intestine were assessed by visual inspection of the records and by polar planimeter measurements of surface areas beneath the tracings.

With individual exceptions, the group showed during the second, third, and fourth hours of observation a decline in peristaltic contractions fluctuating from thirty to thirty-seven per cent. Sudden, striking decreases in activity lasting from five to twenty minutes followed the spontaneous occurrence of spasms. Segmental waves, though difficult to assess, seemed to follow the course of peristaltic waves. "Tone" varied with alterations in the types of contractions and tended to increase slightly

with the passage of time. Most individuals showed a specificity of pattern as regards frequency, amplitude and duration of contractions and "tone."

Without a full appreciation of the spontaneous decline in contractions during long observation periods, the tendency of contractions to be temporarily abolished or decreased following spasms and individual motility variations, it is impossible to evaluate adequately the pharmacologic effects of drugs on intestinal motility. This is particularly true of drugs administered orally. Multiple balloon recording permitted simultaneous assessment of adjacent intestinal segments. Changes in motility appeared not to be conditioned by the administration of placebo as employed in this study. Infrequency of pain prevented its correlation with motility patterns.

Effects of Salt and Protein Restriction on Blood Pressure and Renal Hemodynamics in Hypertensive Patients.

H. CHASIS and (by invitation) W. GOLDRING, E. BREED, A. BOLOMEY and H. W. SMITH, New York, N. Y.

Twelve patients with essential hypertension were selected at random. Observations were made on blood pressure, glomerular filtration rate, renal blood flow and maximal tubular excretory capacity. The patients were maintained on a salt and protein restricted diet identical in composition with the rice diet suggested by Kempner, for from 15 to 98 days. Renal function measurements were made in 10 of the patients; in 9 the rate of glomerular filtration was reduced, in 8 the renal blood flow was decreased, and in 6 the maximal tubular excretory capacity was reduced. In 10 of the 12 patients no lowering of blood pressure was effected by the restricted diet used in this study. In the remaining two patients decrease in blood pressure levels of 24 and 22 mm. Hg systolic and 14 and 14 mm. Hg diastolic occurred. However, in view of the spontaneous variability of blood pressure levels, crudity of the sphygmomanometric method and difficulty in selection of a datum of reference during the control period, we are unwilling to accept as significant such relatively slight and transient reductions as indication of effectiveness of the dietary regime employed in this study.

In view of the adverse effects observed on renal hemodynamics and the transient and insignificant reduction of blood pressure we conclude that salt and protein restriction was ineffective therapy in the 12 hypertensive patients studied.

Studies on the Initiation of Coagulation by Surface Contact. C. LOCKARD CONLEY, ROBERT C. HARTMANN and JOHN S. LALLEY (Introduced by G. Canby Robinson), Baltimore, Md.

Using silicone-treated apparatus blood was obtained from normal human subjects without the use of anticoagulants. The formed elements were removed by high-speed centrifugation at low temperatures. Direct microscopic examination of the undiluted plasma revealed as a rule less than 10 platelets per cubic millimeter. In some instances no platelets were seen. Plasmas prepared in this manner regularly clotted within a few minutes at 37° C.

following the addition of ground glass. Platelet extracts prepared by grinding washed platelets in glass containers also brought about coagulation. However, the concentrated platelet extracts did not cause coagulation to occur more rapidly than did ground glass when added to these essentially platelet-free plasmas. The rate of clot formation following the addition of ground glass was related to the amount of glass added and was independent of the number of platelets or quantity of platelet extract present. The amount of prothrombin converted during coagulation seemed directly related to the amount of platelet material available. When plasma was clotted by ground glass in the virtual absence of platelets, prothrombin consumption seemed negligible. Unlike normal plasma, hemophilic plasma deprived of its platelets failed to clot on contact with glass.

Normal platelet-deficient plasma could be kept in silicone-treated tubes at 37° C. for relatively long periods of time without spontaneous coagulation even though clotting occurred promptly following the addition of ground glass. Although fresh normal plasma invariably clotted on contact with glass, portions of this plasma stored for 24 hours at 2° C. in some instances failed to clot on the addition of ground glass.

These observations suggest that the initiation of coagulation by surface contact may be brought about by alterations produced in the plasma itself and not necessarily by platelet changes.

Effects of Intravenous Reduced Glutathione (GSH) Upon Glycosuria and Hyperglycemia Induced in Man by Adrenocorticotrophic Hormone (ACTH). JEROME W. CONN and (by invitation) LAWRENCE H. LOUIS and MARGARET W. JOHNSTON, Ann Arbor, Mich.

We have reported that sustained glycosuria and hyperglycemia can be produced in man by administration of ACTH and that these manifestations of a developing diabetic state are accompanied by a decreasing concentration of blood glutathione. We have hypothesized that a purine metabolite having an alloxan-like effect is responsible for reducing the intracellular availability of free sulfhydryl groups (necessary for normal function of many enzyme systems), causing functional abnormalities within the islet-beta-cells as well as blocking normal glucose utilization peripherally. In addition to hyperglycemia, ACTH decreases renal tubular reabsorption of glucose, presumably as the result of inhibition of an enzyme within the tubular epithelium.

A thirty day metabolic balance study was made to determine whether or not administration of large amounts of GSH would reverse (during continued ACTH administration) an already established hyperglycemia and glycosuria produced in a normal man. GSH in large amounts was given on the fourth day of a six day ACTH period. Renal glycosuria occurred on the first day of ACTH. Hyperglycemia began on the second day and continued with increasing intensity throughout the entire ACTH period except during the interval when GSH was administered. This reversal was dramatic but transitory, lasting for one to two hours after each injection of GSH.

During these periods the urine was free of sugar. Most striking were (1) sharp elevation of the renal threshold and (2) a fall of the blood sugar level.

Not all of the metabolic effects of ACTH were reversed by GSH. This means that corticoid production was not blocked but that improved performance occurred in those systems requiring free S-H groups for their normal function. Among other reversed effects noted following GSH was a most profound change in the number and character and the peripheral blood cells.

All of these sharp reversals produced by GSH during ACTH administration strengthen our hypothesis and imply important hormonal influences upon enzyme activity.

Observations on the Hemolytic Mechanism in Paroxysmal Nocturnal Hemoglobinuria. WILLIAM B. CROSBY (Introduced by William Dameshek), Boston, Mass.

The red cells in paroxysmal nocturnal hemoglobinuria (PNH) are easily hemolyzed by the action of a heat-labile substance present in normal human plasma. This substance is similar in many respects to complement. Like complement, its hemolytic activity is blocked by heparin, although the amount of heparin needed for this inhibition is somewhat less than that needed to inhibit complement. Titers of 1 : 4,000 will almost completely block the hemolytic system of PNH *in vitro*.

Protamine, a potent heparin antagonist, prevents this heparin inhibition. Yet alone in the hemolytic system, protamine acts like heparin and inhibits hemolysis.

Titration with protamine or heparin in the PNH hemolytic system yields in each case, a sigmoid curve which breaks upward at about 1 : 3,000 and levels off at about 1 : 8,000. When cell suspensions containing the two antagonists in equal concentration are mixed, protamine seems much the stronger. Four parts of heparin cause no inhibition of hemolysis in the presence of one part of protamine.

A patient with PNH was given intravenously fifty mg. of heparin. This at once reduced the ability of his plasma to hemolyze his cells when incubated *in vitro*. During the ensuing six hours the hemolytic potency of his plasma gradually recovered. To a second patient, 80 mg. of heparin were given at the time of a transfusion in the hope of preventing a transfusion reaction to which she was prone. But a violent hemolytic reaction followed. In both of these patients the hemolytic mechanism was blocked *in vitro* by heparin.

Protamine and heparin are antagonistic by virtue of powerful and opposed electrostatic charges. Each alone is capable of inhibiting hemolysis in the hemolytic system in PNH. When both are present together in the hemolytic system they inhibit one another, and hemolysis occurs. Their effect is probably due to inhibition of a complement-like substance present in normal human plasma.

Primary Aseptic Meningitis: A Clinical Syndrome of Diverse Etiology. EDWARD C. CURNEN and (by invitation) JOSEPH L. MELNICK, and ERNEST W. SHAW, New Haven, Conn.

During the summer of 1948 a number of children and young adults were admitted to hospitals in Connecticut and Rhode Island with the clinical syndrome of primary aseptic meningitis. In most instances a diagnosis of poliomyelitis was made. These cases considerably exceeded in number those with paralytic poliomyelitis. The clinical and laboratory findings were studied in selected patients with representative non-paralytic illnesses.

Prominent initial symptoms were fever, headache, and vomiting. Nuchal rigidity and stiffness of the back were common but transitory complaints. The leukocyte counts approximated normal. The cerebrospinal fluid revealed a pleocytosis, usually less than 500 and predominantly lymphocytic; the protein content was normal or slightly elevated.

The course of the illness was brief and uncomplicated. All patients recovered completely. In patients with this syndrome, differentiation of non-paralytic poliomyelitis from mild non-paralytic illnesses due to other causes usually could not be made from clinical findings alone.

Attempts were made to recover the causative agent from representative patients with primary aseptic meningitis. Suspensions of stool from 2 of 14 patients tested induced poliomyelitis in monkeys. Similar suspensions injected into suckling mice resulted in the recovery of a filterable agent resembling that reported by Dalldorf and Sickles. Separate strains were obtained from 5 patients. Attempts to recover this agent from 9 other patients with aseptic meningitis (including the 2 whose stools induced poliomyelitis in monkeys), from 2 patients who developed paralytic poliomyelitis in 1948 in Connecticut, and from 20 patients with other illnesses were unsuccessful. Further efforts are in progress to characterize this agent, to correlate its occurrence with clinical and serological findings, and to determine whether infection by it represents a distinct disease entity.

Physiologic, Metabolic, and Electrolytic Balance Studies of Hypertensive Patients While on the Rice Diet. H. CURRENS, E. A. S. REID, E. A. MACLACHLAN and M. L. TERRY (by invitation) and A. M. BUTLER and P. D. WHITE, Boston, Mass.

In an effort to determine the *modus operandi* of the rice diet two men (one had previously undergone sympathectomy) were studied before and after instituting dietary therapy. The following pertinent observations were made.

The blood pressure fell in one patient after two weeks (174/126 to 160/111) and the other after three months (166/112 to 141/87) on the diet. The addition of nine grams of salt per day to the latter resulted in a rise (164/103).

A negative balance was observed for sodium, chloride, calcium, phosphorus, and magnesium on the diet. One patient had a positive potassium balance of about 20 milliequivalents per day. The serum concentration of these electrolytes remained essentially the same. The negative nitrogen balance was approximately five grams per day during the first week on the diet decreasing to one gram

after three months. The serum albumin fell significantly after three months.

An abrupt fall of the basal metabolic rate of about 12 points was observed after beginning the diet. No significant weight loss was noted. The insensible weight loss per day remained the same.

The plasma volume as measured by the Evans blue dye before and after the institution of the diet was found to remain constant.

Renal clearance tests revealed a subnormal glomerular filtration rate during the control period which decreased after starting the diet. No change was noted in the effective renal plasma flow. The tubular excretory mass was observed to decrease on the diet.

The change in blood pressure observed was not associated with a significant change in plasma volume or serum electrolytes. The addition of sodium chloride resulted in a rise in blood pressure. A persistent negative nitrogen balance was noted.

Metabolic Studies in Infants During Recovering from Vomiting. T. S. DANOWSKI and (by invitation) L. GREENMAN, J. H. PETERS, R. GOW and F. MATEER, Pittsburgh, Pa.

Six infants with pyloric stenosis, together with 1 other with vomiting and diarrhea of undiagnosed origin, have been studied during convalescence by the balance method. The majority had characteristic hypochloremia and alkalosis. Azotemia was present in one. At the start of the individual studies, but following therapy with solutions of saline and glucose, 4 had abnormally low concentrations of serum potassium. The initial serum sodium ranged between 123 and 152 milliequivalents per liter.

Oral intake was then completely withheld, without further vomiting, until the obstruction had been relieved. During this time the patients received parenteral glucose solutions, small amounts of saline, and, in all but one instance, practically no potassium. The potassium intake again became significant, however, upon resumption of oral fluids and food.

During recovery while on either parenteral or oral intake all subjects retained sodium and chloride. The chloride space, assumed at the start to be 15 per cent of the initial body weight for purposes of calculation expanded progressively until, in some instances, it exceeded by a considerable margin the volumes usually assigned to extracellular fluid. Hypokalemia appeared, or usually increased further if already present, in six patients. Low levels developed even though urinary losses were only a fraction of a milliequivalent per day. With potassium administration the urinary excretion increased, but did not equal the intake. This retention points to preexisting deficits and suggests renal conservation of potassium. The data do not identify the renal and extra-renal losses of potassium in the etiology of potassium deficits incurred prior to these studies. They do point, in spite of undue rises in the chloride space employed to partition external balances between cells and extracellular fluid, to a combination of dilution of extracellular fluid and transfer of

potassium into cells as the mechanism of hypokalemia during therapy.

Antifibrillatory Actions of an Alpha-Fagarine Analog (N-Methyl-N-(3-4 dimethoxybenzyl) - B - (4, methoxyphenyl) - Ethylamine - HCL). JOSEPH R. DIPALMA, (by invitation) JOHN E. SCHULTS, RICHARD A. REISS and JOSEPH J. LAMBERT, Brooklyn, N. Y.

The exact chemical structure of α Fagarine is unknown. A new compound, approaching its proposed formula and having similar biological effects and superior in respects to potency with low toxicity has been synthesized.

In cats the new compound is 2.3 times more active than quinidine and 1.3 times more active than α Fagarine in stopping electrically induced auricular fibrillation. The effects on blood pressure, pulse and EKG are similar to quinidine. Nevertheless, its acute i.v. toxicity for cats is less than either quinidine or α Fagarine.

When assayed in humans with normal hearts the Q-T segment is increased on the average by 0.06 sec. with a dose of 100 mgm. and by 0.09 sec. with a dose of 200 mgm. i.m. Similar doses of quinidine in the same patients increased the Q-T segment by 0.01 and 0.03 sec. respectively. This may be taken as good evidence that the drug is capable of increasing the refractory period of heart muscle and that it is more potent than quinidine in this respect.

In 5 patients with chronic auricular fibrillation the f-f interval was increased on the average 28.2 per cent with a dose of 100 mgm. i.m. This slowing of the rate of auricular circus movement is much greater than could be anticipated from a similar dose of quinidine.

Clinical study of 10 patients, 7 with auricular fibrillation, 2 with auricular flutter and 1 with ventricular tachycardia permit the following conclusions. Two cases of auricular fibrillation and one with flutter were restored to a regular sinus rhythm. In one instance restoration occurred with a dose of only 50 mgm. i.m. A very serious disadvantage of the drug is that like α Fagarine it has a tendency to initiate ventricular ectopic foci. Because its chemical structure is known the possibility exists of developing a derivative of equal potency but lacking this undesirable feature.

A Method for Estimating, preoperatively, the Function of Thyroid Tumors; Its Significance in the Diagnosis and Treatment. BROWN M. DOBYNS and BENGT SKANSE (Introduced by Edward D. Churchill), Boston, Mass.

An estimate of function of a discrete thyroid nodule contributes in a major way to the diagnosis and treatment of such a goiter. Many studies indicate that function of such nodules can be related to their avidity for radioiodine. An in vivo technic has been devised for detecting the degree of concentration of radioiodine in various parts of the thyroid. This technic permits an estimation of the relative function of discrete nodules as compared with the remaining thyroid.

The conventional Geiger-Muller counters are incapable of locating point sources within the thyroid because of the anatomical and physical relationships involved.

A specially constructed directional counter has been found capable of locating and differentiating relative concentrations of radioiodine over small areas of the thyroid. In more than 50 patients the results of observations made with this technic were found to agree with radioautographs made from the same tissue removed at operation. Such differentiation in the function of thyroid nodules contributes significantly to the intelligent treatment of these goiters.

Hyperfunctioning adenomas of the thyroid are recognized as a source of clinical or masked hyperthyroidism which may produce cardiac damage. Their recognition and removal are often followed by remarkable improvement. This method of preoperative study has been of value in recognizing many such lesions.

By this method of locating the concentrated radioiodine, an incidental non-functioning nodule in the thyroid of Graves' disease may be distinguished from a hyperfunctioning adenoma producing hyperthyroidism. Since the management of these two problems may differ, the observations are important.

In our experience cancer of the thyroid collects less radioiodine than normal thyroid tissue. The finding of a nodule with a decreased or absent function eliminates the large group of hyperfunctioning nodules and thus increases our suspicion of malignancy.

Pulmonary Circulatory Dynamics in Mitral Stenosis and Left Heart Failure. J. W. DOW (by invitation), L. DEXTER, and (by invitation) F. W. HAYNES, J. L. WHITTENBERGER, and B. G. FERRIS, Boston, Mass.

Pressures in the pulmonary artery and pulmonary "capillaries" were measured with Hamilton and saline manometers. Blood flow through the lung was determined by the direct Fick principle. Pulmonary arteriolar resistance was determined by the Poiseuille equation.

In patients with mitral stenosis and left heart failure, pulmonary "capillary" pressure was elevated. In mild cases, the pulmonary artery pressure was likewise elevated, while the pulmonary artery-pulmonary "capillary" pressure gradient, blood flow, and pulmonary arteriolar resistances remained normal. In more advanced stages, the pulmonary "capillary" pressure at rest exceeded the osmotic pressure of plasma, the pulmonary artery pressure became extremely elevated, and the pulmonary arteriolar resistance rose to high levels due in part to a decreased cardiac output but mainly to a high pulmonary artery-pulmonary "capillary" pressure gradient.

It is concluded that in mitral stenosis and left heart failure (1) the pulmonary "capillary" pressure is elevated, sometimes exceeding the osmotic pressure of plasma, (2) the pulmonary artery pressure rises to a similar extent in early cases and in advanced cases the rise is out of all proportion to the rise in pulmonary "capillary" pressure due to constriction of the pulmonary arterioles thus producing an obstruction to blood flow proximal to the pulmonary capillary bed.

Effect of Treatment on Renal Functions and Electrolyte Excretion in Congestive Heart Failure. DAVID P.

EARLE, JR., (by invitation) SAUL J. FARBER and JOHN D. ALEXANDER, and LUDWIG W. EICHNA, New York, N. Y.

Serial observations on renal functions, daily electrolyte excretions and cardiovascular status were made on 2 patients during various phases of congestive heart failure. They were maintained on regular hospital diet and moderate ward activity, and received no therapy other than digitalis products. Glomerular filtration rate (GF), renal plasma flow (PF) and TmPAH were reduced while the filtration fraction (FF), venous pressure (VP) and weight were elevated in both during the congestive failure phase. As edema was lost there was fall in VP and FF and some improvement in GF and PF. These changes, however, were slight and the functions did not return to normal. Electrolyte excretions paralleled water balance, but at no time did electrolyte excretions fall to very low levels.

The acute effects of intravenous digoxin on the above functions were also studied. Rather prompt increases in water and sodium excretions were noted, even in the absence of significant change in GF, PF or FF. Water and electrolyte excretions appeared to be inversely related to the VP. In instances where VP fell but remained elevated well above normal, little or no increase in water or electrolyte excretion was observed. Similarly, marked diuresis was observed following intravenous injection of aminophyllin, without significant change in renal hemodynamics.

These data are compatible with the thought that impaired water and electrolyte excretion in congestive heart failure is not necessarily related primarily to the commonly observed changes in renal hemodynamics. It appears that increased renal venous pressure may play an important role in retention of water and sodium in congestive heart failure of man. Data bearing on the possibility that cardiac glycosides may act on renal tubular mechanisms of electrolyte reabsorption is also presented.

Effect of Protein Starvation on the Clinical Course, Liver Function, and Liver Histochemistry of Patients with Active Liver Disease. RICHARD ECKHARDT, NORMAN ZAMCHECK, RICHARD SIDMAN and GEORGE GABUZDA (Introduced by Maxwell Finland), Boston, Mass.

To clarify the role of protein in the treatment of human liver disease, 3 deeply jaundiced patients with active alcoholic cirrhosis (fatty) were provided with food adequate in calories but not sufficient in protein to maintain nitrogen equilibrium (0.5, 0.2, and 0.0 grams per kilogram body weight daily for 24, 8, and 11 days, respectively). Although negative nitrogen balance persisted, each manifested clinical improvement, a decrease in liver size and tenderness, a rapid fall in serum bilirubin and in urine bile, and a progressive decrease in urine urobilinogen (measured in 2 patients). Nitrogen balance became positive when 1.0 to 1.4 grams of protein per kilogram daily were given. Improvement continued, but appeared less marked because of the extent of previous change. The serum albumin concentration and thymol turbidity and

flocculation tests, although frequently abnormal, showed no consistent pattern of change.

Histochemical studies were made of liver tissue obtained by biopsy from the last 2 patients before and during the low protein period and during the increased protein feeding period. Five "protein starvation" biopsies showed an initial low cellular protein content which further diminished, moderate to marked fat which remained unaltered, and shrunken cells. Necrosis was not observed. The three "protein repletion" biopsies showed a marked increase in protein content, a progressive decrease in fat, and a return of cell size and appearance toward normal. Liver glycogen progressively increased during both periods of study, while fibrosis (minimal) remained unchanged.

It is concluded that, under the conditions of this study, improvement in clinical status and in liver function occurred in spite of negative nitrogen balance occasioned by diets grossly deficient in or devoid of protein. Liver histology, however, failed to reflect this improvement, and morphologic improvement appeared only with the provision of adequate exogenous protein and the maintenance of positive nitrogen balance.

Studies on the Pathogenesis of Nephrotic Edema. HOWARD A. EDER and FRANCIS P. CHINARD (by invitation), HENRY D. LAUSON, and (by invitation) ROGER L. GREIF, ALMA HILLER, GEORGE C. COTZIAS and DONALD D. VAN SLYKE, New York, N. Y.

The availability of concentrated human albumin for intravenous administration has made possible extensive studies of the sequence of events occurring during the development of nephrotic edema. The initial event is proteinuria. The renal mechanism involved has been examined in nephrotic patients by measurements of the albumin clearance under conditions of changing plasma concentrations following infusion of albumin. It has been found that the excretion is proportional to the plasma concentration, and that the albumin/creatinine clearance ratio is constant over a wide range of concentrations, unless the blood volume increases, in which case the ratio also increases. Our present concept is that in nephrosis albumin is filtered through the glomerular membrane in abnormally large amounts, and that almost all of the filtered albumin is excreted, tubular reabsorption being relatively slight. The continued excretion of albumin results in hypoalbuminemia, and, in accordance with the Starling hypothesis, the plasma volume decreases absolutely as well as relative to the extracellular fluid volume. The diminished plasma volume is believed to be responsible for the decreased renal excretion of water and salt which is the immediate cause of edema. This belief is based on the observation that the excretion of these substances rises sharply when the plasma volume is expanded following the administration of albumin. The fact that the rate of glomerular filtration is increased at the same time suggests that the retention of salt and water during accumulation of edema may be attributed at least in part to a decrease in the rate of glomerular filtration, relative to the intrinsic (i.e., non-hormonal) tubular reabsorptive activ-

ity with respect to water and salt. In addition, there is some evidence to suggest that increased secretion of salt-active adrenal hormones and antidiuretic hormone may play a role in the retention of salt and water.

The Mechanism of Anemia and Its Influence on Renal Function in Chronic Uremia. CHARLES P. EMERSON, JR., and BELTON A. BURROWS (Introduced by Chester S. Keefer), Boston, Mass.

The assumption that anemia in uremic patients is due to inadequate blood production rather than to excessive blood destruction has been tested in four cases of chronic nephritis with marked anemia and azotemia. Hematologic and metabolic studies were performed before and after successive transfusions of marked red cells which in each instance could be distinguished by means of selective agglutination technics from those of the recipient. The relative rates of erythropoiesis and hemolysis were estimated from the results of serial hematologic examinations, including separate measurements of the concentration and total volume of circulating donor and recipient red cells, the degree of reticulocytosis and of bilirubinemia. Parallel determinations were made of the concentrations of non-protein nitrogen and electrolyte constituents of the blood, the total volume of extracellular fluid, and the volume and composition of the urine, as a basis for evaluating the influence of anemia and the effect of corrective blood replacement on renal function.

The data obtained indicated that anemia in these cases was mainly attributable to a depression of erythropoiesis, but also suggested that a contributory factor in its pathogenesis was the presence of excessive hemolytic activity, evidenced by the unusual rapidity with which donor red cells were destroyed following transfusion, their elimination from the blood of the recipient occurring at 1.5 to 3 times the normally expected rate. With respect to the clinical and metabolic effects of massive transfusions it was impossible, in this series of patients, to demonstrate any correlation between the degree of renal decompensation and the grade of coexisting anemia. Complete correction of the latter by means of artificial replacement therapy failed in all instances to lessen or to increase the severity of the uremic manifestations or to influence the progress of the underlying renal disease.

The Insulin Glucose Tolerance Test—An Improved Procedure for the Detection of Hypoglycemia Unresponsiveness in Pituitary and Adrenal Insufficiency. FRANK L. ENGEL and (by invitation) JAMES L. SCOTT, Durham, N. C.

The usefulness of the insulin tolerance test for the diagnosis of conditions characterized by hypoglycemia unresponsiveness is limited by the danger of serious hypoglycemic reactions in those patients in whom the test should be most valuable. Smaller doses of insulin often yield equivalent results requiring repetition of the test. To overcome these objections advantage has been taken of the fact that hypoadrenal and hypopituitary patients not only exhibit hypoglycemia unresponsiveness after insulin but also a de-

played response to oral glucose during hypoglycemia. By giving 0.8 gm. of glucose per kilogram orally to the fasted subject 30 minutes after 0.1 unit insulin per kilogram intravenously, hypoglycemic manifestations are aborted but hypoglycemia unresponsiveness is still apparent. Blood sugars are determined before insulin and at 30, 60, 90, 120, and 180 minutes. The results are expressed as per cent of the fasting blood sugar. In 9 normal individuals and 9 patients with non-endocrine diseases the mean maximal rises in blood sugar after glucose were 149 and 128 per cent of the initial blood sugar at 90 minutes with a return to the fasting level at 180 minutes. In 7 observations on Addison's disease and 6 on panhypopituitarism the mean maximal rises were only 82 and 84 per cent of the initial blood sugar respectively and occurred at 180 minutes. None of the latter patients achieved a blood sugar after insulin and glucose as high as the lowest peak in the two control groups. As a group, 6 patients with anorexia nervosa had a mean response not significantly different from the controls. However, one patient fell clearly into the hyporesponsive range and one was borderline. Three patients with primary myxedema showed normal curves. Neither pretreatment with lipoadrenal cortex, intravenous cortical extract (50 ml.) or epinephrine before and after insulin restored the response of the hyporesponsive patients to normal.

Skin Reactions to Toxoplasma Antigen in People without Known History of Infection. HARRY A. FELDMAN and ALBERT B. SABIN, Cincinnati, Ohio.

One hundred and forty-two residents of the Cincinnati area ranging in age from 3 months to 81 years were surveyed for their reaction to the intracutaneous injection of toxoplasma antigen prepared from infected chorioallantoic membranes of chicken eggs. The positive reactions, consisting of red, indurated, swollen, tender and itching lesions ranging in size from 60 × 50 mm. to 10 × 10 mm. (the latter being relatively rare), reached their maximum in 30 to 48 hours. The incidence of positive reactions among at least 20 individuals in each age group listed was as follows: 0-4 years—0; 5-9 years—5%; 10-19 years—14%; 20-29 years—20%; 30-39 years—50%; 40-49 years—65%; 50-81 years—65%. A positive skin test was invariably associated with demonstrable toxoplasma antibody in the serum. Toxoplasma antibody in varying titer was also found in the serum of 7 of 18 persons (39%) with negative skin tests. Further evidence in favor of the high incidence of toxoplasma antibody among the "normal" adult population was obtained when a 15-20 fold concentrated, commercial preparation of gamma globulin prepared from the plasma of more than 20,000 American adults was found to contain toxoplasma antibody in a titer of 1:256 as determined by the dye test. No agent having an antigen in common with toxoplasma and capable of giving rise to antibodies for this protozoon parasite has been found thus far. Therefore, one must consider the possibility that inapparent infection with toxoplasma may be very widespread, although it is rather curious that the incidence of antibodies (and presumably infection) should rise so sharply after the 20th year of life. The toxoplasma

skin test is not useful for diagnosis because a strongly positive test bears no relationship to titer of antibody and a negative test is encountered too often in the presence of antibody.

Studies on the Isolation and Identification of Beta-Hemolytic Streptococci from Throat Swabs. A. E. FELLER, (by invitation) GEORGE F. BADGER, JOHN H. DINGLE, (by invitation) RICHARD G. HODGES, and CHARLES H. RAMMELKAMP, Cleveland, Ohio.

Investigations of the role of β -hemolytic streptococci in respiratory disease require (1) sensitive methods for detecting the organisms on throat swabs, especially when they are present in small numbers, and (2) reliable methods for characterizing the organisms so isolated. For the latter purpose, classification according to the serological groups of Lancefield is essential.

The purposes of the present study were (1) to compare the sensitivity of the conventional streak plate method with the technique devised by Pike employing selective media for the detection of β -hemolytic streptococci on throat swabs, (2) to devise a simple method for predicting that a certain organism can be grouped serologically, short of making an extract of each organism and testing it against group specific sera, and (3) to determine the reliability of the rather simple enzyme technique devised by Maxted for preparing extracts of the organisms for serological identification.

Comparison of the streak plate method with the Pike technique showed that 96 per cent of 327 consecutive isolations of groupable streptococci were accomplished by the Pike method; in only 4% of the swabs was the streak plate positive when the Pike plate was negative. After evaluating many procedures it was found that β -hemolysis of sheep blood agar (surface or deep colonies) is a simple and reliable criterion for determining that a streptococcus can be grouped serologically (Lancefield). Organisms failing to produce β -hemolysis on sheep blood agar have thus far not been groupable. Comparison of the enzyme technique of Maxted with the conventional formamide method of preparing extracts of streptococci for serological grouping has demonstrated essentially complete agreement when employing streptococci producing β -hemolysis on sheep blood agar. The Maxted technique is extremely simple and the extracts react with specific sera in 15 to 30 minutes.

Iron Metabolism in Hemochromatosis. C. A. FINCH (Introduced by James P. O'Hare), Boston, Mass.

Observations have been made relating to the diagnosis, pathogenesis, and treatment of hemochromatosis.

Iron excess may be recognized by sternal puncture, by the per cent utilization of radioiron for hemoglobin production, and by determining the per cent saturation of the iron binding protein of the serum. The latter has proved particularly useful in the recognition of hemochromatosis.

Since little iron is excreted in man, hemochromatosis must be associated with increased iron absorption. In animals it has been possible by dietary means to produce excessive iron absorption, indicating that the normal mu-

cosal regulation of iron absorption is not effective in certain circumstances. It is also suggested by similarity in iron distribution in these experimental animals, in patients with multiple transfusions and in idiopathic hemochromatosis, that the iron in all instances represents storage iron. Accordingly several patients have been repeatedly phlebotomized. In contrast to normal subjects who rapidly exhaust their iron reserves and develop anemia, patients with hemochromatosis are able to give up large amounts of iron without evidence of iron deficiency.

These studies provide methods of identifying enlarged stores of iron at an early stage in the clinical course of hemochromatosis and by phlebotomy a means of removing the excessive iron found in this disease.

Sweat Sodium Concentration in Thyrotoxicosis. FRANCIS W. FITZHUGH and ARTHUR J. MOSELEY (by invitation), and ARTHUR J. MERRILL, Atlanta, Ga.

Conn has demonstrated an inverse relationship between the sweat sodium concentration and the activity of the sodium-retaining factor of the adrenal cortex. In the course of other studies, we found a low sweat sodium concentration in 10 of 11 patients with thyrotoxicosis. Our average for 26 determinations in 18 normal subjects was 49.1 mEq./l. with a range of 15 to 92 mEq./l., all but 4 being between 24 and 70. The average for 10 of 11 patients with thyrotoxicosis was 14.2 mEq./l. with a range of 2.4 to 26.6. The remaining patient had a sweat sodium concentration of 46.2 mEq./l. The BMR's of these patients ranged from +42 to +80.

Five normal individuals were placed on thyroid extract, 2 grams daily. Three of these had a drop in sweat sodium concentration from 51 to 31, 61 to 32.5, and 92 to 22 on the 7th, 7th, and 4th days respectively. One subject had a low control level of 19 mEq./l. and his sodium concentration rose to 25 on the 7th day. The fifth individual showed an increase from 32 to 63 mEq./l. on the 10th day. Two of those who had a fall in sweat sodium concentration were restudied with daily sweat sodium determinations. One of these had a marked diminution on the 9th day from 38 to 19.5 followed by a rebound to 42 on the 11th day. The other showed no significant change. Reciprocal changes occurred in the sweat potassium concentration. No change was noted in the number of circulating eosinophils or in the BMR.

The determination has been of assistance in diagnosis in two patients with thyrotoxicosis whose BMR's were unsatisfactory and in whom the diagnosis was uncertain.

In summary, a new method is offered for the diagnosis of thyrotoxicosis which shows little overlapping with the normal.

Metabolic Studies on Cushing's Syndrome. P. H. FORSHAM and E. FLINK (by invitation), K. EMERSON, JR. and G. W. THORN, Boston, Mass.

Eosinopenia (less than 50 cells per cu. mm.) appears to be characteristic of Cushing's syndrome and an elevated urinary uric acid: creatinine ratio (greater than 0.8) frequently occurs. Such changes have been reproduced in normal subjects given adrenocorticotrophic hormone and

in patients with Addison's disease on Compounds E and F. Following successful treatment, these values return to normal and their change constitutes a helpful indicator of the effectiveness of therapy.

The refractoriness of certain patients with Cushing's syndrome to the salt retaining action of desoxycorticosterone (Soffer) has been confirmed. In a study on the metabolic effects of Compound E in patients with Addison's disease it was found that 100 mg. of Compound E daily led to slight sodium and chloride retention. In contrast, such patients when treated with desoxycorticosterone and showing marked sodium retention exhibited a paradoxical increase in sodium and chloride excretion when given additional Compound E. On the basis of these observations on the competitive renal action of desoxycorticosterone (a powerful salt retainer) and Compound E (a weak salt retainer), it is suggested that the desoxycorticosterone acetate fastness of certain patients with Cushing's syndrome may be due to the blocking action on the renal tubule of an excess of adrenal steroids of the 11,17-oxytype.

Electrolyte Abnormalities in Chronic Congestive Heart Failure; Effects of Administration of Potassium and Sodium Salts. CHARLES L. FOX, JR., CHARLES K. FRIEDBURG and ABRAHAM G. WHITE (Introduced by A. R. Dochez), New York, N. Y.

Plasma, edema fluid and urine electrolytes were studied during congestive failure. Plasma sodium was significantly below normal in twenty-seven of thirty patients. Plasma chlorides and potassiums ranged from below to above normal; chlorides, however, were relatively increased. Urinary sodium was low whereas potassium was high. Repeat measurements after recovery in five patients showed that the low sodiums had increased, whereas chloride and potassium shifted toward normal.

During mercurial diuresis sodium chloride excretion increased but sodium in urine was usually hypotonic; chlorides however equalled or exceeded sodium. Potassium excretion increased fivefold.

The data indicated that failure is frequently associated with hypotonic extracellular fluid excessive in chloride and that during recovery, relatively more water, chloride and potassium are excreted than sodium. The possibility that some of the water excreted was of intracellular origin is also supported by the rise in the non-colloidal extracellular osmotic pressure which might draw water from cells.

Accordingly, sodium lactate was given to raise extracellular sodium and bicarbonate concentrations, and potassium acetate to raise intracellular potassium and bicarbonate. Up to 400 mEq. of each were administered orally for periods up to thirty days to six patients in failure. Mercurial diuretics previously required were omitted. Loss or no gain in weight occurred despite positive balances of sodium and potassium. Sodium excretion increased markedly although subnormal plasma sodium initially decreased further. Shift of water from intra- to extracellular compartments is thereby suggested.

Individual administration of the chloride and acetate of Na or K increased weight two to six kilograms therefore

mercurials were required after each single salt period. Simultaneous administration of sodium chloride and potassium acetate caused minimal weight gain despite positive Na, Cl, and K balances.

Extracellular hypotonicity may be associated with intracellular hypotonicity and depletion, hence separate readjustment of either compartment augments edema. Intracellular abnormalities may also be important in failure.

Quantitative Studies on Pulmonary Absorption of Aerosols Made with Solutions of Sodium p-Amino Hippurate. WILLIAM FRANKLIN and CLARENCE DENTON (by invitation), and FRANCIS C. LOWELL, Boston, Mass.

In the course of laboratory studies on the effect of aerosolized drugs and allergenic extracts in pulmonary disease, the need arose for a method of determining, with some degree of accuracy, the amount of material retained by the subject. The use of penicillin (blood levels) or radioactive materials (tissue concentrations) was considered and discarded as poorly adapted to the problem. Promising results have been obtained with aerosolized solutions of sodium p-amino hippurate. This compound is well tolerated and is rapidly absorbed and quantitatively excreted in the urine. The procedure followed was (1) to expose the subject to a measured volume of a standard aerosol of PAH, (2) to collect material not retained by the subject, and (3) to collect the urine over a six hour period, with determination of the amount of PAH after hydrolysis with acid.

The aerosol, produced by nebulizers receiving oxygen delivered at an accurately measured rate, was passed over concentrated sulfuric acid in order to increase stability by partial drying into a spirometer (which provided the flexibility required by the intermittent removal of the aerosol during the subject's respiration) and through a flutter valve to the subject. Expired aerosol passed through a second flutter valve and was collected in a highly efficient impinger. Measurements were made of the PAH delivered, the PAH in the collecting impinger, the valve assembly, and the urine.

Repeated tests have shown that agreement within 10 per cent was obtainable between (1) the amount delivered and (2) the sum of that found in the urine, the expired air and valve assembly. The following results were obtained in one test with subject inhaling aerosol for ten minutes: amount of PAH delivered—96 mgms.; amount in expired air and valve assembly—54 mgms.; amount in urine—42 mgms.

Studies with a New Method for Quantitative Measurement of I^{131} Content of the Thyroid Gland in Man. A. STONE FREEDBERG, ALVIN URELES and MARVIN VAN DILLA (Introduced by H. L. Blumgart), Boston, Mass.

Direct measurement of uptake of radioactive iodine by the thyroid has been attempted by two techniques of external counting: (1) a Geiger-Mueller counter is placed against the neck over the thyroid gland; (2) the tube is at varying distances from the neck. In both instances, the variation in thyroid size and location (depth geometry

and absorption) have not permitted quantitative measurement of I^{131} content.

With 4-6 platinum cathode Geiger-Mueller counters connected in parallel and arranged in a circle 36-120 cm. in diameter, a central source of radiation was moved about within a sphere 8-32 cm. diameter concentric with the circle of counters; the maximum variation in counting rate was 5 per cent. When the source was surrounded by muscle, bone, water and saline in quantities approximating the human neck there was no significant change in counting rate. With a constant amount of radioactivity in volumes varying from 5-350 cc. in different shaped containers no significant change in counting rate was observed. Identical amounts of I^{131} in 5 cc. and in 2,000 cc. of water placed in gallon jugs showed a decrease of 5 per cent in the counting rate in the latter instance.

Preliminary studies in patients with varying thyroid gland size are consistent with mock up experiments. With a 4 tube circle of 104 cm. diameter, a central "sphere" is present approximately 20 cm. in diameter within which movement of the head and neck gave no significant change in counting rate. Thyroid uptake and urinary excretion has been measured by this method in euthyroid subjects and in patients with various thyroid disorders and will be reported.

It is concluded that quantitative measurement of I^{131} content of the thyroid gland in man is obtained by the above described method independent of the size and location of the gland.

Evaluation of the Dye Method for Estimating Blood Volume in Man. EDWARD D. FREIS, JOSEPH R. STANTON and CHARLES P. EMERSON (Introduced by William L. Fleming), Boston, Mass.

The higher estimation of blood volume using T-1824 as contrasted with labeled red cells has cast doubt on the validity of dye methods for determining blood volume. In man the mixing time of T-1824 was relatively complete within the first three minutes following which there was a uniform and therefore detectable disappearance of circulating dye which could be corrected by extrapolation. Repeated injections of T-1824 at short intervals indicated that there was no undetected dye loss during the initial mixing period. Simultaneous determinations of arterial and hepatic venous concentrations of dye failed to demonstrate significant escape of T-1824 in the liver.

Measurement of the relative velocities of dyed plasma and identified red cells during a single circulation through a peripheral vascular bed revealed that in the capillaries the mean velocity of the cells was greater than that of plasma. The capillary hematocrit, therefore, must be lower than the large vessel hematocrit. These observations support the validity of the dye method for measuring plasma volume and indicate that the high values obtained for total blood volume with T-1824 are not due to undetected escape of dye from the circulation but to the discrepancy in the proportion of red cells and plasma in large versus small vessels.

A Quantitative Study of the Rate of Renal Excretion of Digitoxin. MEYER FRIEDMAN and (by invitation) RENE BINE, JR. and SANFORD O. BYERS, San Francisco, Calif.

Hitherto, it has not been possible to determine with quantitative methods the role of the kidney in the excretion of digitalis glycosides. However, by means of the embryonic duck heart method, as little as one microgram of digitoxin could be detected in the 24 hour urinary output of the rat. This technique therefore enabled us to study the rate of renal excretion of digitoxin in this animal after its parenteral administration.

A series of 10 rats were given by intramuscular injection 0.1 meg. of digitoxin per gram of body weight (or approximately 15 meg. per rat) and the urine was collected daily for three days. Each 24 hour urine sample was analyzed for its digitoxin content. No digitoxin could be detected in the initial 24 hour urine collection of any rat, indicating that less than one microgram of digitoxin had been excreted during this period. Likewise no digitoxin was found in the 48 or 72 hour urine sample of any rat.

A series of 12 rats therefore were injected with 1.0 meg. of digitoxin per gram of body weight (approximately 225 meg. per rat). It was found that there was an average excretion of 6.0 meg. of digitoxin (2.5 per cent of amount injected) during the first 24 hours following injection. No digitoxin, however, was detected in any of the urine samples collected during the 48 or 72 hours following injection.

The above results indicate that the renal excretion of digitoxin in the rat is either nil or relatively insignificant even after the administration of relatively huge amounts of the drug.

Effect of Lipotropic Agents, Testosterone Propionate, and Dietary Protein upon Nitrogen Balance in Patients with Liver Disease. GEORGE J. GABUZDA and RICHARD D. ECKHARDT (by invitation) and CHARLES S. DAVIDSON, Boston, Mass.

Four patients with Laënnec's cirrhosis and one with infectious hepatitis were maintained on basal diets providing 25, 50, 75, 100 and 100 grams of protein daily. Initial control nitrogen balances averaged -4.2, +1.6, +3.3, +5.4, and +6.8 grams daily, respectively. The effect of supplements of choline and methionine, of testosterone, and of dietary protein upon these balances was determined.

The oral administration of 4.5 to 9.0 grams each of choline chloride and dl-methionine simultaneously daily for 6 to 9 days to these 5 patients did not have a nitrogen sparing effect above that which could be accounted for by retention of part of the nitrogen contained in these agents.

Subsequent to control periods following the administration of choline and methionine, 25 mgm. of testosterone propionate was administered intramuscularly daily for 6 days to the 3 patients with intakes of 50, 100, and 100 grams of protein daily. Their ability to respond to a protein anabolic stimulus was indicated by increased nitrogen retentions of 1.2, 2.6, and 1.4 grams daily.

After the reestablishment of nitrogen balances comparable to initial control periods, increases in dietary protein of 50 grams daily in the 3 patients on basal intakes of 50, 75, and 100 grams of protein were accompanied by increases in daily nitrogen retention averaging 2.6, 3.8, and 7.1 grams, respectively. The patient in negative nitrogen balance while receiving a 25 gram protein basal diet promptly established nitrogen equilibrium when the protein intake was increased to 50 grams, although previously choline and methionine had failed to spare nitrogen.

Although testosterone propionate had a protein anabolic effect in these patients with liver disease, it is concluded that positive nitrogen balance was most effectively achieved by adequate dietary protein. No appreciable nitrogen sparing action could be attributed to choline and methionine in the quantities used.

The Effect of Anoxic Anoxia on the Human Kidney. MORTON GALDSTON, EUGENE Y. BERGER, and SEYMOUR A. HOROWITZ (Introduced by J. Murray Steele), New York, N. Y.

Several factors, among them anoxia, may play a part in retention of salt and water in heart failure. The following experiments were designed to test the effect of renal anoxia per se on these phenomena. In 7 subjects with normal cardiovascular, respiratory systems, renal function during inhalation of 14 per cent oxygen (arterial oxygen tension of approximately 50 mm. Hg), a degree of anoxia which results in barely perceptible changes in circulatory and respiratory dynamics, was compared with renal function during the preceding and subsequent periods breathing room air. Similar studies were conducted in 2 emphysematous subjects with arterial blood oxygen tensions of approximately 50 mm. Hg while breathing room air and again, while breathing 100 per cent oxygen. Periods breathing room air were considered as the anoxic periods. Observations on respiration and circulation were also made.

Renal plasma flow remained the same or tended to increase during anoxia in all normal subjects. In the emphysematous subjects it decreased during inhalation of 100 per cent oxygen. Change in filtration rate during anoxia was not consistent in direction or degree. The most pronounced effect of anoxia on renal function was an invariable and frequently marked increase in the rate of excretion of sodium, chloride, and water. The alterations in respiration and circulation which occurred during inhalation of 14 per cent and 100 per cent oxygen do not seem to account for the changes in renal plasma flow. The conclusion is drawn that anoxic anoxia alone does not appear to result in reduction of renal plasma flow or retention of salt and water. Other electrolyte changes studied will be presented.

Transfer to Normal Red Cells of an Agglutinin Demonstrable in the Acidified Sera of Patients with Acquired Hemolytic Jaundice. FRANK H. GARDNER (Introduced by Thomas Hale Ham), Boston, Mass.

Studies of defibrinated blood samples from 15 patients with acquired hemolytic jaundice have shown agglutina-

tions of N_{15} were found in the uro- and coproporphyrin isolated during different periods. The data will be discussed in relation to hemoglobin metabolism.

The Neuromuscular and Ganglionic Blocking Action of bis-Trimethylammonium Decane and Pentane Dibromide (C 10 and C 5). DAVID GROB and DUNCAN A. HOLADAY (by invitation) and A. McGEHEE HARVEY, Baltimore, Md.

Paton and Zaimis studied the effects in animals of polymethylene bis-trimethylammonium salts of the general formula $(CH_3)_3N-(CH_2)_n-N(CH_3)_3(Br)_2$. They found the C 10 derivative ($n=10$) to be a neuromuscular blocking agent and the C 5 derivative ($n=5$) an autonomic ganglionic blocking agent. The administration of these compounds to man has shown that they are very effective in their blocking action at these sites and are clinically useful. The intravenous injection of 2.5 mg. of C 10 in normal subjects resulted in almost complete paralysis of the muscles of the extremities, with relatively slight weakness of swallowing, speech, and respiration. C 10 was administered to more than 60 patients for the relaxation of skeletal muscles during convulsive shock therapy and surgical anaesthesia. The effective dose of C 10 was one-third that of d-tubocurarine on a weight or molar basis, and it had relatively less effect on the bulbar and respiratory muscles. The action of C 10 was of shorter duration than that of d-tubocurarine. C 10 caused a progressive decline in the muscle action potential in response to nerve stimuli. In contrast to d-tubocurarine it produced no histamine-like effects. C 5 produced evidence of autonomic ganglionic block in doses one-tenth to one-twentieth that of tetraethylammonium, on a weight or molar basis. The intravenous administration of 5 to 20 mg. of C 5 resulted in marked postural hypotension in most normal and hypertensive subjects, and a prompt fall in blood pressure in some hypertensive subjects. These effects persisted for as long as 3 to 6 hours.

The Role of the Kidney in the Pathogenesis of Malignant Hypertension as Indicated by a Study of Dogs Maintained with an Artificial Kidney after Nephrectomy, Implantation of the Ureters into the Bowel or Vena Cava, and Ligation of the Ureters. ARTHUR GROLLMAN, E. E. MUIRHEAD and JOHN VANATTA (Introduced by Gladys Fashena), Dallas, Texas.

That the kidney plays a role in the animal economy in addition to its recognized function as an excretory organ has been inferred, particularly in relation to hypertension. However, direct experimental evidence bearing on this problem has not been possible since nephrectomy or abolition by other means of renal function leads to death from excretory insufficiency before other evidences of renal dysfunction are manifested. The present study is based on observations of more than 150 dogs subjected to (1) bilateral nephrectomy, (2) bilateral ligation or severance of the ureters, or (3) implantation of one ureter into the small bowel or into the vena cava with subsequent removal of the contralateral kidney. Survival of the animals was extended by application of an artificial kidney, the use of

which shall be described. Nephrectomy results in an elevation of blood pressure and pathological changes in the kidneys characteristic of malignant hypertension. These observations, which are contrary to those generally held on the basis of short survival studies, offer direct evidence against the view that renin or other pressor substances play a role in the pathogenesis of hypertension.

In the presence of renal tissue as when a ureter is implanted into the duodenum or vena cava and the contralateral kidney removed, no elevation in blood pressure ensues. However, pathological changes induced by the accumulation of catabolic waste products from the organism are induced. The experiments permit certain conclusions as to the relation of the presence of renal tissue, blood pressure changes and uremia in the pathogenesis of the structural changes observed in malignant hypertension.

The Application of Electron Microscopy to the Study of Connective Tissue Constituents. JEROME GROSS (Introduced by Walter Bauer), Boston, Mass.

The electron microscope because of its high resolving power is capable of revealing the form of aggregation of macromolecules in certain biological systems. When this organization is of a constant and regular pattern one is provided with an accurate fingerprint of the substance which can be used for identification and study of formation and alteration.

The fibrous components of the connective tissue, collagen and elastin, are particularly suitable subjects. Up to the present only normal tissues have been studied, in part for the purpose of providing a base line for the eventual examination of pathological material. An extensive study of collagen from many tissues of many animals has revealed a characteristic fibrillar unit with an axial repeating period of 640 A units and a distinctive pattern of intra-period fine structure.

A study of the elastic tissue of the mammalian aorta, ligamentum nuchae and fish swim bladder has revealed characteristic non-banded branching fibers which when digested by trypsin give rise to long filaments 120A in width in the form of tight, evenly coiled helices produced by the interlacing of finer threads approximately 70A in width. The pitch of the helix, approximately 530A was the same for filaments from human, rabbit and rat aorta as well as ligamentum nuchae. Boiling the tissue in dilute acid to remove collagen prior to enzyme digestion did not affect the filaments.

The influence of pH and temperature on the state of aggregation and helical morphology of these structures will be discussed.

It is concluded that the elastic fiber is a two component system composed of bundles of trypsin-resistant filaments of characteristic form and size imbedded in a trypsin-sensitive, heat-resistant "amorphous" binding matrix. The possible relationship of the elastic properties of the tissue to this structure will also be discussed.

The Effects of Sympathectomy and Other Sympathetic Procedures on the Cerebral Circulation in Essential Hypertension. JOSEPH H. HAFKENSCHIEL and

HENRY A. SHENKIN (by invitation), SEYMOUR S. KETY and WILLIAM A. JEFFERS, Philadelphia, Pa.

Quantitative data on blood flow, oxygen consumption and vascular resistance of the brain were obtained in hypertensive patients before and after bilateral lumbo-dorsal sympathectomy (9 patients), differential spinal sympathetic block (17 patients), parenterally administered dihydroergocornine (7 patients) and bilateral stellate ganglion block (5 patients).

Cerebral vascular resistance was significantly decreased following thoracolumbar sympathectomy, differential spinal block and intramuscular dihydroergocornine. Cerebral vascular resistance was not lowered after block of the stellate ganglia bilaterally.

These findings are interpreted as indicating that the increased resistance in the brain of essential hypertension is partially reversible. No evidence has been adduced that this resistance is mediated through the stellate ganglia, but our data do not rule out completely a neurogenic mechanism. It is of interest that the cerebral blood flow and cerebral oxygen metabolism are unchanged with the hypotension of sympathectomy and dihydroergocornine; the cerebral blood flow decreased significantly only when the blood pressure was acutely and severely reduced by differential spinal block.

It is concluded that procedures which produce a prolonged but moderate fall in arterial blood pressure in hypertensives do not bring about a sustained reduction of the cerebral blood flow when measured in the supine position since the vessels of the brain are capable of compensatory dilatation. When the reduction in blood pressure is sudden and excessive, however, the compensation may be incomplete.

Analysis of Mechanism of Cooley's Anemia by Transfusion Survival of Erythrocytes. HENRY E. HAMILTON and RAYMOND E. SHEETS (Introduced by Elmer L. DeGowin), Iowa City, Iowa.

The survival of normal erythrocytes and those from patients with Cooley's trait were studied after transfusion into normal subjects, persons with Cooley's trait, and patients with Cooley's anemia by the Denstedt modification of the Ashby differential agglutination technique. A new method of analysis was employed in which the ratio of the concentrations of the donor's cells to those of the recipient was used to indicate fluctuations in the plasma volume of the recipient, the relative rate of disappearance of transfused erythrocytes, the abnormal destruction of the recipient's cells, and temporary erythropoietic arrest.

It was found that normal erythrocytes normally survive transfusion into subjects with Cooley's trait and Cooley's anemia. The red blood cells from persons with Cooley's trait persist normally in the circulation of healthy subjects and in subjects with Cooley's trait. They also survive a normal span in patients with Cooley's anemia. Analysis of the donor-recipient-cell ratio demonstrates that the mechanism of anemia in Cooley's disease is the rapid destruction of the patient's own erythrocytes. Similar hemolytic episodes of milder degree were also noted in persons

with Cooley's trait. In addition, periods of diminished and augmented rates of erythropoiesis were noted in normal subjects, persons with Cooley's trait, and patients with Cooley's anemia.

(The data will be presented from twelve blood transfusions in which the method was applied in the study of Cooley's anemia. Controls are derived from many other transfusions studied in normal subjects and patients with various blood dyscrasias.)

Effect of Influenza Viral Infection on Ciliary Movements in the Mouse. CARL G. HARFORD and (by invitation) MARY HARA, St. Louis, Mo.

Cells of respiratory epithelium of man and other animals are equipped with cilia and the movements of these hair-like structures are thought to be an important means of natural resistance to bacterial infection. One theory concerning inception of respiratory infection is that viruses destroy the cilia-bearing cells of the epithelium thereby enabling bacteria to gain a foothold. In previous experiments, it was found that lowered pulmonary resistance of the mouse to inhaled pneumococci is associated with the lesion due to infection with influenza virus. The purpose of the present study was to determine whether viral impairment of ciliary action in the bronchi contributes to this lowered resistance since influenza virus is known to attack the bronchial epithelium.

In addition to special stains for demonstration of cilia, their movement was visualized directly in thin slices of fresh lung which were mounted as wet preparations in saline. When the margins of bronchi were viewed under the microscope with reduced light or by phase microscopy, the rapid ciliary beat was seen clearly.

In the viral lesion of 5 days duration, it was found that regeneration of bronchial epithelial cells had taken place and the cilia appeared normal both in morphology and motility. Therefore, in order to observe the maximal effect of viral infection on ciliary action, many lethal doses of virus were employed and observations were made after 2 to 3 days so that the greatest number of epithelial cells would be in the stage of necrosis. Even under these conditions, the majority of ciliated cells were not involved and profuse ciliary movement was observed regularly.

These findings do not support the theory that viruses affect resistance by interference with ciliary action.

Liver and Kidney Function in Rocky Mountain Spotted Fever. GEORGE T. HARRELL, Winston-Salem, N. C.

Chemotherapy or specific immunotherapy is administered to eradicate an etiologic agent. Specific therapy, as opposed to supportive therapy, may not prevent or control physiologic disturbances induced by an infection. From 1942-1947, liver and kidney function tests were performed on 16 children and 10 adults with Rocky Mountain spotted fever. Tests were done on admission, at the clinical peak of the disease, during convalescence and after discharge.

Liver: Less than 3 gm. of galactose was excreted in 11 tests. In 21 tests, less than 27 gm. (oral) or 67 gm. (IV) of hippuric acid was excreted in 13 instances.

Bromsulfalein was retained 6 times in 18 tests. Serum bilirubin exceeded 4 mg. per cent only once. Prothrombin time was elevated markedly in 2 patients. Serum albumin was below 3.5 gm. per cent in 18 patients.

Kidney: Urea clearance was below 70 per cent in 9 of 13 patients. Phenolsulfonphthalein excretion exceeded 65 per cent (50 per cent in children) in 9 patients. The NPN exceeded 40 mg. per cent in 7 patients. Slight albuminuria was occasionally observed. RBC were found in the urine in 5 patients and casts in 8.

Liver damage, related in degree to the clinical severity of the disease, was greatest by hippuric acid test and occurred with or following the clinical peak. BSP, prothrombin, and albumin alterations occurred during the acute febrile phase. Function returned to normal with convalescence.

Kidney damage was less marked in degree, unrelated to the clinical severity, occurred before or during the clinical peak and returned to normal with convalescence. No glomerulonephritis was seen. Azotemia is probably due to fluid and circulatory disturbances rather than renal damage.

In 18 patients a high protein diet protected against changes in serum albumin and hippuric acid excretion; it did not decrease renal function but occasionally overloaded the kidney.

The mechanism responsible for the changes is obscure.

The Response to Adrenocorticotrophic Hormone in Patients with Scleroderma and the Therapeutic Use of Testosterone. SAUL HERTZ and (by invitation) PETER H. FORSHAM, Boston, Mass.

Scattered evidence has pointed to an endocrine factor in scleroderma, but none put forth to date incriminates any specific glandular defect. Suggestive features of a positive type include the marked incidence of hypercreatinuria, reduced creatine tolerance tests, low urinary 17-ketosteroid excretion and a relationship of onset of periods of exacerbation to menstruation, menopause, etc. Predominance of the disease in the female sex, and in prepubertal males, has been impressive. Disorders of calcium metabolism (ectopic calcification), negative nitrogen balance and marked wasting have been emphasized. We have confirmed these findings in our series. The creatinuria, myopathy, negative nitrogen balance, pigmentation and occasional low serum sodium and chloride levels are compatible with some degree of gonadal or adrenal hypofunction. That this might be secondary to pituitary underactivity is suggested by low FSH titres, I¹³¹ uptake by the thyroid and 17-ketosteroid excretion.

Seven cases have been studied from the standpoint of 17-ketosteroid excretion, creatine tolerance and responses to epinephrine and ACTH.

17-Ketosteroid values on 24-hour urines in this group ranged from 1.2 mg. to 6.0. However, 48-hour tests with ACTH (40 mg. per day) led to a marked rise in 17-ketosteroid excretion and other evidences of "S" factor activation.

Since ACTH is not available for therapeutic application, we chose to observe 4 patients on high dosage of tes-

tosterone propionate intramuscularly. Dosage ranged from 25 to 50 mgs. \times 3 per week. Gradual disappearance of skin lesions, as well as improvement in esophageal involvement (radiologic evidence) took place. Rapid weight gain and increased appetite and strength together with the establishment of a positive nitrogen balance occurred. Therapy was continued to the point of development of edema; slight hirsutism and masculinization of the voice were encountered. These subsided quickly after cessation of therapy and the skin lesions showed no recurrence four to five months after the end of therapy.

The Pulmonary Vascular Resistance. JOHN B. HICKAM (Introduced by Eugene A. Stead, Jr.), Durham, N. C.

Normally the pulmonary arterial pressure is low and little affected by changes in blood flow. In congestive failure the pressure is high and may be greatly increased by exercise without change in flow. It is difficult to interpret these observations in terms of the state of the pulmonary vessels because the pulmonary arterial pressure also depends on the blood flow and the pulmonary venous pressure. The latter can not usually be measured. The present report presents data obtained from 4 patients with atrial septal defect in whom it was possible to catheterize both pulmonary arterial and venous systems and to measure blood flow, pressure gradient, and pulmonary vascular resistance.

In 2 subjects without apparent pulmonary vascular disease, the resistance was extremely low (0.6 to 0.9 mm. Hg/l./min.). Blood flows of 15 and 20 l./min. were maintained by gradients of 13 and 12 mm. Hg. One subject with congestive failure and pulmonary arterial hypertension had a flow of 15 l./min. with a gradient of only 4 mm. Hg. This indicates that the high pulmonary arterial pressure resulted from transmission of a high pulmonary venous pressure back through the pulmonary vascular bed. The low gradient suggests passive dilatation of the bed. Exercise caused a large rise in pulmonary arterial pressure, two-thirds of which resulted from an increase in venous pressure and one third from an increase in vascular resistance. One subject had pulmonary vascular disease and a high resistance (80 times that of the preceding subject).

The observations provide quantitative data on the wide potential range of pulmonary resistance and suggest the means by which congestive failure produces pulmonary arterial hypertension.

Experimental Evidence on the Mechanism of Diabetic Ketosis. LAWRENCE E. HINKLE, JR., and GEORGE A. CONGER (by invitation) and STEWART WOLF, New York, N. Y.

In a study of 25 human subjects with diabetes mellitus, approximately 50 instances of clinical ketosis were observed to occur in a setting of emotional conflict and in the absence of other pertinent factors including infection. Moreover, day to day observation of these subjects both in and out of the hospital yielded a close correlation between life situation, emotion, and the metabolic state as

reflected by glycosuria, ketonuria, insulin requirement, and the symptoms of diabetes.

In an experimental study of nine of the subjects, quantitative measurements of blood ketone and glucose concentrations and concomitant determination of urine volume and glucose were made before, during, and after an interview in which intense emotional conflict was engendered. Ages of the patients varied from 14 to 60 years, and insulin requirements from none to 100 units per day. The chemical determinations were made on either peripheral venous blood or on blood withdrawn directly from a catheter introduced into the hepatic vein. In all cases a significant elevation of blood ketones, as well as a marked increase in the urine volume and rate of urinary glucose excretion, occurred during the traumatic interview. In the most severe diabetics the rapidity and degree of the increase in blood ketones and urine sugar was greatest, but nevertheless a marked degree of ketosis was produced in one of the mildest diabetics when the traumatic conflict situation was prolonged. The level of the blood glucose also fluctuated significantly, and was usually lower at the end than at the beginning of the experimental period.

Thus, significant emotional conflict has been shown to be associated with a rise in the blood ketone level and a simultaneous "washing out" of glucose through diuresis. The evidence indicates that such a mechanism is commonly involved in the decompensation of diabetes and the production of clinical ketosis.

The Usefulness of the Prompt Direct Reacting (1') Serum Bilirubin in the Study of Mild or Latent Jaundice. F. W. HOFFBAUER, Minneapolis, Minn.

During the last four years the fractional serum bilirubin determination according to the Ducci-Watson modification of the Malloy-Evelyn method, has been widely applied in the study of patients with hepatic, biliary tract, and hematologic disorders. The method is informative at any level of the serum bilirubin, but has demonstrated greater usefulness in mild or latent jaundice. Therefore, for the purpose of the present study, the cases included have had total serum bilirubins not exceeding 3 mg. per 100 cc.

The level of the prompt reacting (1') serum bilirubin has been very helpful in demonstrating hepatic abnormality or low grade biliary obstruction where the total serum bilirubin was increased but slightly or not at all. In a number of instances of minimal regurgitation jaundice, the increase in prompt reacting serum bilirubin was well correlated with bromsulfalein retention and positive cephalin cholesterol flocculation (parenchymal liver disease), and with increases of alkaline phosphatase and serum cholesterol (extrahepatic biliary obstruction). Conversely, in pure retention jaundice, increases in the indirect reacting (T-1') serum bilirubin, with slight or no increase in the 1' value, have been quite uniform.

Data correlating the essential clinical features and the results of other liver function studies will be analyzed and discussed.

Experimental Evidence on the Relative Effects of Life Stress and Inhaled Pollen in Hay Fever. THOMAS H.

HOLMES and THEODORE F. TREUTING (by invitation) and HAROLD G. WOLFF, New York, N. Y.

An experimental attempt was made to clarify the relative importance of stressful life situations and inhaled pollens in the pathogenesis of hay fever. In 30 subjects, 15 of whom had had hay fever, repeated quantitative studies of nasal function were made under uniform conditions in a room in which a known concentration of pollen was circulated.

Nasal hyperfunction characterized by varying degrees of hyperemia, swelling and hypersecretion of the membranes as well as eosinophilia in the nasal secretions and circulating blood occurred in all subjects, "sensitive" or "normal," exposed to mixed ragweed pollen when the circumstances were appropriate. When nasal function was average, neither "sensitive" nor "normal" subjects reacted to mixed ragweed pollen with sufficient evidence of nasal hyperfunction to produce symptoms. However, when there was preexisting nasal hyperfunction from whatever cause, both groups reacted to the pollen with marked nasal hyperfunction, weeping and sneezing. Thus during difficult life situations productive of conflict typical hay fever attacks followed pollen inhalation. Conversely, it was possible during pollen inhalation in the absence of frank hay fever to induce an attack by a discussion of significant personal problems and to induce subsidence of the attack by reassurance while the pollen is still being inhaled.

Unilateral procaine block of the stellate ganglion in 10 subjects yielded evidence that nasal hyperfunction engendered by conflict situations was mediated through parasympathetic fibers in the greater superficial petrosal nerve. Inhalation of pollen following this procedure precipitated the signs and symptoms of unilateral rhinitis which spared the non-hyperfunctioning membrane on the uninjected side. It was concluded that "sensitive" individuals differ from normals only in degree, that pollen or stressful life situations may induce nasal hyperfunction in either with associated local and circulating eosinophilia and symptoms of rhinitis. The various factors provocative of nasal hyperfunction with symptoms of hay fever thus exert an additive effect.

Quantitative Estimate of Vasomotor Tone in the Human Extremity with Comparative Studies of the Sympathetic Blocking and Adrenolytic Properties of Tetraethylammonium, Priscol, and Dihydroergocornine. SIPLEY W. HOODLER, JOHN W. AVERA, SAMUEL G. MCCLELLAN and WILLIAM J. LITTLE (Introduced by Richard H. Lyons), Ann Arbor, Mich.

Presumably complete blockade of sympathetic vasomotor tone in the human subject without marked organic vascular disease was produced by means of spinal anesthesia, caudal anesthesia, lumbar paravertebral block, or within 24 hours after sympathectomy. Blood flow to the foot, as measured by the venous occlusion plethysmograph, was regularly increased to an average of 14 times control values. In contrast, tetraethylammonium (500 milligrams intravenously) increased blood flow to an average of 7 times resting levels and produced no vasodilatation after sympathectomy or after intra-arterial administration. In

usual clinical doses it therefore produced an approximately 50 per cent blockade of sympathetic vasoconstrictor tone and had no local vasodilator action.

Priscol (30-50 milligrams intravenously) induced a three fold increase in blood flow in the foot and a two fold increase in the innervated and denervated hand. Blood flow likewise was increased after intra-arterial injection. In this dosage the effects of the drug can in large measure be accounted for by a local vasodilator action, although slight sympatholytic activity can not be excluded.

Dihydroergocornine (0.25 - 1 milligrams intravenously) caused a slow and delayed increase in blood flow to 2.6 times resting levels in the foot and 2.1 and 2.4 times resting levels in innervated and denervated hand respectively. In this dosage the drug has little or no sympatholytic effects and may produce vasodilatation after conversion into a vasodilator agent or by altering existing vaso-regulatory mechanisms which are not mediated through sympathetic pathways.

Adrenolytic activity was measured by determining the effect of the drugs on the vasoconstrictor response to intra-arterial injection of epinephrin. When tetraethylammonium, DHO, or benzodioxane (16 milligrams) was administered intravenously, the response to intra-arterial epinephrin was not altered. On the other hand priscol intravenously had a moderate adrenolytic effect. When high local concentrations of the last three drugs were achieved by intra-arterial injection, significant adrenalin blocking action was demonstrated.

Iron Metabolism Studies in Normal Subjects and in Patients having Blood Dyscrasias. REX HUFF and THOMAS HENNESSEY (by invitation), and JOHN H. LAWRENCE, Berkeley, Calif.

Shemin and Rittenberg have provided a method for accurate determination of the life of the red cell. With the need in mind for a method of determining the rate of production of hemoglobin; iron turnover in plasma and red cells of normal subjects and patients having polycythemia, leukemia, and refractory anemia has been studied. Total subjects numbered 30.

Iron 59 (80-480 micrograms) was administered intravenously. The plasma iron level was not significantly altered; thus the clearance as measured by the rate of decrease of labeled iron in the plasma was effected at a constant plasma iron concentration. The coefficient of clearance (fraction of plasma volume cleared of iron per hour) was as low as 0.09 in a refractory anemia patient and as high as 3.84 in a polycythemia patient. The normal value was 0.35.

The appearance of iron 59 in the circulating red cells was usually of a double exponential nature. The time required for a final level to be reached varied from 5 to 40 days. The trend was toward a more rapid appearance in the polycythemics and some of the leukemics.

The fraction of the total dose present in the circulating red cells at equilibrium was computed on the basis of a circulating red cell mass determined by tagged cell methods or by estimation. The fraction utilized varied from 0.05 in a refractory anemia patient to 0.95 in a patient

who had had a severe hemorrhage. The average normal was 0.80.

The amount of iron incorporated into red cells per day varied from 220 mg. in a polycythemic to 2.9 mg. in a refractory anemia patient. The average normal value was approximately 20 mg.

The authors believe that here is a method for the determination of the rate of hemoglobin production in normal and pathologic states.

The Role of the Hypothalamus in the Pituitary-Adrenal Cortical Response to Stress. DAVID M. HUME (Introduced by Francis D. Moore), Boston, Mass.

The mechanism responsible for increased secretion of anterior pituitary adrenocorticotrophic hormone after non-specific trauma and stress, and the consequent rise in the titre of circulating adrenal cortical hormone has been studied in dogs and man. Trauma, insulin, chemical irritants, and epinephrine have been used as the stimulators of the pituitary-adrenal cortical system. The fall in circulating eosinophils has been used as an indicator of increased adrenal cortical activity, as this has been shown previously to be a measure of 11-17-oxysteroid output by the adrenal cortex, and to be dependent on the secretion of anterior pituitary adrenocorticotrophic hormone. The integrity of the anterior pituitary and adrenal cortex has been shown to be essential for the eosinopenic response to stress.

Anterior hypothalamic lesions in the supra-optic nucleus producing diabetes insipidus do not interfere with the normal eosinopenic response to stress; nor does divesting the pituitary of its vascular and nervous connections with the intact hypothalamus. However, specific localized electrolytic lesions placed in another area of the anterior hypothalamus abolish the usual eosinopenic response to stressing agents, even in the presence of an intact pituitary; and significant alterations in response follow lesions in the afferent tracts to this area. An extract of the hypothalamus has been prepared which on injection is capable of producing good eosinopenic responses in normal animals and also in animals whose hyperthalamic lesions render them incapable of responding to any of the stressing agents tested. These findings suggest the presence of a hormonal mechanism located in the anterior hypothalamus which, when activated in stress, will release a substance capable of causing an increased secretion of adrenocorticotrophic hormone by the anterior pituitary. In the absence of this mechanism no increased secretion of adrenal hormone can be detected in response to stress by the methods employed.

Electrolyte and Renal Function Studies in Lower Nephron Nephrosis. LLOYD T. ISERI, THOMAS M. BATCHELOR, A. J. BOYLE, and S. D. JACOBSON (by invitation) and GORDON B. MYERS, Detroit, Mich.

With the aid of the Beckman flame photometer and emission spectrograph, rapid determinations of plasma and urinary sodium and potassium were obtained and utilized as a guide to therapy in patients with lower nephron nephrosis. Simultaneous mannitol, para-aminohippurate,

sodium and potassium clearances were determined periodically. Impaired tubular reabsorption of sodium with relatively high urinary sodium concentration was demonstrated during the early stages and restoration to normal reabsorptive capacity during recovery. Markedly negative nitrogen balances were also observed during recovery.

In some of the cases, renal functional studies were correlated with the pathological findings in material obtained by renal biopsy or at autopsy. The relationship between pre-renal azotemia, lower nephron nephrosis, and bilateral cortical necrosis of the kidneys will be discussed.

Studies of the Principle in Liver Effective in Pernicious Anemia. VII. The Augmentative Effect of Accessory Factors on the Therapeutic Activity of Vitamin B12. BERNARD M. JACOBSON and (by invitation) RONALD C. BISHOP, Boston, Mass.

Evidence has accumulated that the therapeutic action of liver extract in pernicious anemia depends upon the presence of a *primary* factor, exerting by itself only slight or moderate hematopoietic effect, and upon the presence of five chemically distinct *accessory* factors which, in the absence of the primary factor, are therapeutically inert, but which augment the activity of the primary factor. The accessory factors include *l*-tyrosine, a peptide, xanthopterin, tryptophane, and guanosine.

The availability of crystalline vitamin B12 made possible the study of this material as a primary factor. Erythrocyte regeneration curves were constructed from data in the literature and from personal observations concerning sixteen patients who received vitamin B12 parenterally in a calculated average daily dose of 2.1 micrograms. When contrasted with similar curves representing the effect in a larger number of patients of commercial liver extract in a calculated average daily dose of 2.1 U.S.P. units, it becomes evident that the hematopoietic effect of pure vitamin B12 is inferior to that of a comparable dose of commercial liver extract. Erythrocyte regeneration following the administration of a comparable amount of non-crystalline primary factor together with accessory factors similarly was more rapid than that induced by vitamin B12. Thus, in a range of initial erythrocyte levels from 1.50 to 1.99 millions *per cu. mm.*, the average daily erythrocyte increment, in thousands *per cu. mm.*, were as follows: commercial liver extract, 78; primary factor together with accessory factors, 86; vitamin B12, 59. Similarly, in a range from 2.50 to 2.99 millions *per cu. mm.*, the average daily increment was 63, 61, and 31, respectively.

The augmentative effect of accessory factors on the action of vitamin B12 is illustrated by data of individual cases.

The Role of the Spleen in Radiation Injury. LEON O. JACOBSON, Chicago, Ill.

In an attempt to study the significance of the spleen in recovery from or compensation for radiation injury, four groups of mice were prepared. Group I consisted of untreated controls. Mice in groups II, III and IV were

anaesthetized with nembutal and the spleens brought out through an abdominal incision with the main pedicle intact. Groups III and IV mice were irradiated with 600 r whole body X radiation (250 kv.) except that during the irradiation the mobilized spleens of group IV were placed in a lead box with an opening for the pedicle only. After irradiation the spleens of groups II, III and IV mice were returned to the abdominal cavity.

The widespread destruction of hematopoietic tissue which developed in mice that received 600 r inclusive of the spleen (group III) produced a severe anemia, leucopenia and thrombocytopenia. Ectopic erythrocytopoiesis in the lead protected spleens of mice given 600 r (group IV) compensated with such rapidity for the marrow destruction that no anemia of significance developed. Ectopic granulocytopoiesis and megakaryocytopoiesis in the lead protected spleens compensated significantly but at a slower pace and less completely for the marrow destruction.

A marked and sustained decrease in the amount of lymphatic tissue occurred in the lead protected spleens (group IV) as ectopic hematopoiesis increased. This decrease in lymphatic tissue may be an indirect effect of irradiation.

The rapidity with which erythrocytopoiesis transferred from the X ray damaged marrow to the lead protected spleen in the absence of anemia suggests that the mechanism of stimulation of erythrocytopoiesis under the conditions of this experiment may involve some factor or factors other than or in addition to the accepted hemoglobin oxygen relationship.

Preliminary studies indicate that a significantly larger number of the irradiated animals with a lead protected spleen (group IV) survive than irradiated animals without spleen protection (group III).

Degradation of "Prothrombin-Converting Factor" in Sera of Individuals Receiving Dicumarol. RALPH F. JACOB and ROBERT BAYS (Introduced by Howard B. Slavin), Rochester, N. Y.

A study of the differential clotting action of *fresh serum* for fibrinogen and whole 0.01 M oxalated plasma, reveals that the serum coagulating factor is not thrombin, but a "prothrombin-converting factor." This factor requires ionized calcium before it can be activated from an inert precursor existing in oxalated plasma or circulating whole blood; while the conversion of prothrombin to thrombin by the serum factor takes place in the virtual absence of ionized calcium. Immediately after coagulation has been initiated by thromboplastin or platelets, a residuum of "prothrombin-converting factor" remains in the expressed serum. In individuals with a normal quantity of plasma prothrombin, the rate of disappearance (or degradation) of the serum "prothrombin-converting factor" is constant. In sera of individuals receiving dicumarol, the degradation rate of the serum "prothrombin-converting factor" usually varies directly with plasma prothrombin concentration. By applying the formula

$$\frac{\log c_1 - \log c_2}{T_1 - T_2}$$

wherein $ct_1 - ct_0$ is clotting time (seconds) of serum for plasma and $T_1 - T_0$ is elapsed time (minutes) for a given change to take place, one can express degradation rate (D.R.) as a unit.

The sera and plasmas of a series of patients receiving dicumarol were assayed daily for prothrombin (1 and 2 stage technique) and serum "prothrombin-converting factor" degradation rate. Good correlation between the two determinations existed, although the measurement of the degradation rate of serum "prothrombin-converting factor" was no substitute for conventional methods of prothrombin assay.

Immunologic Studies of an Iron Binding Protein in Human Serum. B. V. JAGER (Introduced by M. M. Wintrobe), Salt Lake City, Utah.

The immunologic properties of a crystalline β_1 globulin (Fraction IV-7-4) have been examined. This protein, isolated by Cohn and coworkers from plasma, has been found to have the property of binding with iron *in vitro*. A number of rabbits were immunized to this fraction. From a study of the antigen-antibody interactions of these antisera with the homologous antigen, Fraction IV-7-4 appeared to be immunologically homogeneous.

Standardized antisera were obtained by determining the amount of precipitate formed (antigen + antibody) after addition of varying known quantities of the IV-7-4 antigen. With this calibrated antiserum the amount of immunologically reactive IV-7-4 antigen in any unknown human serum can be determined by the quantitative precipitin technique.

As measured immunologically, the amount of IV-7-4 antigen in 14 normal human sera ranged from 0.21 to 0.31 grams per 100 ml. The mean value was 0.27 grams or 3.4 per cent of the total serum protein. Similarly, immunologic values were obtained for the sera of a number of pregnant women and a number of patients with acute or chronic infections. The values were increased in the pregnant women and reduced in the patients with infections. This was in accord with the alterations in the chemically determined total iron binding capacity of these sera.

The data are interpreted as indicating that the IV-7-4 protein present in human serum comprises all or nearly all of the iron binding protein.

Metabolic Changes in Heat Acclimatized Men during Abrupt Exposure to a Very Cold Climate. ROBERT E. JOHNSON and CHAUNCEY G. BLY (by invitation), ROBERT M. KARK and (by invitation) C. FRANK CONSOLAZIO, Chicago, Ill.

Thirty-two healthy young men, acclimatized for six months to Florida weather and unaccustomed to cold weather and its hardships, were taken by air from Florida (mean temperature $+57^\circ$ F.) to a very cold climate without layover, in January. On arrival in the subarctic, they were isolated in "survival areas." Studies were intensive for the first 24 hours (mean temperature -26° F.), and less intensive for 11 more days. Two questions were

asked. What metabolic changes are manifest in untrained, unacclimatized men during abrupt exposure to extreme cold, even with adequate clothing and environmental protection? For such changes can unifying explanations be found in the literature on cold and heat acclimatization, the catabolic phase after injury, or the "adaptation syndrome"?

Statistically significant responses during the first 24 hours included: transient hypothermia; diuresis, with negative water balance; hemoconcentration, with increases in serum protein, hemoglobin and hematocrit; eosinophilopenia and lymphopenia; neutrophil leukocytosis, with increase in the percentage of immature forms; hyperuricemia, hyperphosphatemia and hyperkalemia; hyponatremia and hypochloremia; transient retention of sodium and chloride, with transient hyperkalemia; and diminution of ascorbic acid in the blood and increase in the urine. Most of these changes reverted to normal in 48 hours. Statistically significant responses in the last six days of exposure included: increase in kidney and adrenocortical efficiency, a test dose of water being excreted rapidly at very low specific gravity; continued eosinophilopenia and lymphopenia; and continued hyperuricemia and hyperphosphatemia. Complete balance data yielded no convincing evidence of a catabolic phase.

The present changes have many similarities to those after injection of the adrenocorticotrophic hormone, and to the "general adaptation syndrome" of animals during stress.

Immunological Studies on Patients with Pneumococcal Pneumonia Treated with Penicillin. WILLIAM S. JORDAN (Introduced by John H. Dingle), Cleveland, Ohio.

Immunological studies of patients and animals with pneumococcal infections have shown that the naturally occurring production of antibodies is not affected by therapy with sulfonamide drugs. Meager data are available for patients treated with penicillin.

The immune response of 44 patients with pneumococcal pneumonia treated with penicillin was measured by agglutination and mouse protection tests. The results indicated that the antibody response of these patients was comparable to that occurring after spontaneous recovery or recovery following treatment with sulfonamides.

Two patients, one infected with type VIII and one with type I pneumococci, were treated within 2 and 3 hours of the acute onset of symptoms respectively. Neither patient developed a demonstrable pulmonary lesion or showed a rise in antibody titer. No other cases treated this early were observed. Of two cases treated within 7 hours of acute onset, both developed mouse protective antibodies and one developed agglutinins. Twenty-four cases received penicillin within 2 to 28 hours of the acute onset of symptoms. Nineteen of the 24 cases, or 79 per cent, showed demonstrable changes in antibody titers. This percentage response is comparable to that which occurred in the patients treated later than 28 hours after onset and parallels the response previously observed in patients not treated with penicillin.

Correlation of Changes in Renal Circulation with Metabolic Balances of Electrolytes and Nitrogen during Recovery from Congestive Cardiac Failure. A. KATTUS, A. GENECIN, J. H. SISSON, C. MONGE, B. C. SINCLAIR-SMITH, and E. V. NEWMAN (Introduced by Alan M. Chesney), Baltimore, Md.

Two edematous patients with congestive cardiac failure were followed during recovery on bed rest and digitalis with metabolic balances of sodium, chloride, potassium and nitrogen. Periodic determinations of renal plasma flow (RPF) and glomerular filtration rate (GFR) were made.

One patient was observed for four months, 24 days on metabolic balances. There was negative sodium and chloride balance for 14 days, the weight and venous pressure falling to normal. Potassium and nitrogen balances were markedly positive during negative sodium balance. More potassium was retained than could be theoretically associated with the nitrogen stored, possibly indicating repair of cellular damage incurred during congestive cardiac failure.

GFR remained within normal limits throughout the four months of observation. RPF rose and filtration fraction (FF) fell during recovery. Three months later after reaccumulation of edema, GFR remained normal, RPF had fallen and FF had risen.

Another patient showed marked sodium chloride loss in four days, the weight falling 4 kilograms, followed by nine days of sodium chloride retention without increase in weight. Equilibrium was then established. Exercise daily for the next 11 days caused seven days of sodium chloride retention, followed by equilibrium. There was potassium and nitrogen equilibrium throughout.

GFR was 50 per cent and RPF 33 per cent of normal with an average FF of 0.40 throughout the balance study. Later the patient's rhythm was reverted from auricular fibrillation to sinus rhythm whereupon GFR rose from 80 to 100 cc./min.

It is concluded that major changes in the body balances of sodium chloride and water may occur at both normal and reduced glomerular filtration rates. In each patient major shifts in salt balances, weight and venous pressure were not accompanied by significant change in glomerular filtration rate. The edematous state was associated with a high filtration fraction due to a low renal blood flow.

Factors Influencing Removal of Bacteria from the Blood Stream. GRACE P. KERBY, BERNARD C. HOLLAND and SAMUEL P. MARTIN (Introduced by W. C. Davison), Durham, N. C.

Factors influencing the removal of bacteria from the blood stream have been studied effectively by a method of combined venous catheterization and bacteremia induced by continuous bacterial infusion. The sites of removal of the bacteria are determined in the anesthetized dog from the bacterial counts of samples of blood removed simultaneously from femoral artery and from veins draining the organs studied.

The major removal of bacteria is accomplished in the splanchnic circulation, the liver and spleen showing equal

efficiency in the process. Removal during hind limb circulation may be of minor importance. No organisms are lost on circulation through the lungs.

Splanchnic removal rate is markedly and significantly decreased for a short period of time by thorotrast blockade.

The basic efficiency of the normally functioning removal mechanism varies widely with the bacterium used, being much greater in the dog for *Escherichia coli* and *Micrococcus aureus* than for *Klebsiella pneumoniae*. Arterial levels of 400 bacteria per ml. are reduced to 100 per ml. with each circulation through the splanchnic area. Sustained bacteremias clear within 15 to 30 minutes after bacterial infusion is discontinued.

Active immunization of the animal increases significantly the removal rate of *Klebsiella pneumoniae*. Administration of normal homologous plasma to the normal dog does not alter removal rate, but administration of equal amounts of homologous immune plasma results immediately in a striking increase in efficiency of splanchnic removal.

These alterations in efficiency of removal of bacteria from the blood stream unquestionably influence the ultimate course of the bacteremia. The extent of possible alteration and the exact mechanisms by which the removal is achieved and altered in the splanchnic area offer fruitful possibilities for further study. The present work points again emphatically to the importance of consideration of both parasite and host factors in any such continued investigation.

Studies in Protein Metabolism with the Aid of S³⁵-Labeled-Methionine. LAURANCE W. KINSELL, SHELTON MARGEN, HAROLD TARVER, JULIE MCB. FRANTZ and ERIN K. FLANAGAN; with the technical assistance of VERNON T. THOMPSON and ROBERT V. DEAL (Introduced by T. L. Althausen), Oakland, Berkeley and San Francisco, Calif.

S³⁵-labeled-methionine has been administered to normal males and to patients with the following entities: (1) Chronic Liver Damage, (2) Idiopathic Hypoproteinemia, (3) Cushing's Syndrome. Incorporation of the labeled material in plasma protein, as well as its excretion in urine and stool, have been quantitated (in most instances as one part of protein balance studies).

From the results obtained, one may tentatively conclude that both the idiopathic hypoproteinemia syndrome and Cushing's syndrome are characterized by a more than normal rate of initial plasma protein formation (as evidenced by incorporation of S³⁵) followed (certainly in the former and probably in the latter) by excessive catabolism, at a rate such that net protein deficiency results.

The three patients with chronic liver damage so far studied show a diminished rate of incorporation of the labeled material into plasma protein, and a subsequent rate of disappearance not unlike that observed in the normal.

Urinary sulfate excretion data are in excellent accord with the preceding observations.

Chloromycetin in the Treatment of the Acute Manifestations of Brucellosis. VERNON HENRY and FRANCISCO

RUIZ-SANCHEZ (Introduced by Paul Reznikoff), New York, N. Y.

Twelve adult patients with acute manifestations of brucellosis have been treated with chloromycetin. All but one of these individuals were treated in Guadalajara, Mexico, and the majority of the infections were caused by *Br. melitensis*. All of the patients were febrile and acutely ill when antimicrobial therapy was started. The pretreatment illness was less than 90 days in 8 of the patients and ranged from 7 to 12 months in the remainder.

The diagnosis of brucellosis was established by demonstration of bacteremia in six patients and by a significant elevation in antibody titer in the others.

Appropriate clinical, bacteriologic and serologic observations were made during the acute illness and during the ensuing three months.

In general, chloromycetin was administered for six or ten days, in daily dose of 50 to 100 mg. per kg. while febrile, and 25 mg. per kg. thereafter.

Clinical improvement after therapy was dramatic. In every case temperature and symptoms rapidly diminished in the first three days of therapy. The average duration of fever was only 2.0 days, except for one individual who made an unsatisfactory response after six days of treatment with low doses. When retreated with higher doses, his course was comparable to that of the other patients.

The chloromycetin results can be compared with results observed following the aureomycin treatment of brucellosis by Spink and his associates and by the present writers. The immediate response of the patients treated with chloromycetin was indistinguishable from the response observed after aureomycin therapy.

Relapse was not uncommon following short periods of therapy with either drug. In the chloromycetin-treated series, relapse occurred within six weeks of the cessation of therapy in five of the twelve cases. The effect of a considerable prolongation of therapy upon the incidence of relapse is under investigation at present.

The Effect of Radiation on Total Coproporphyrin Excretion. HENRY J. KOCH, JR., TIMOTHY R. TALBOT, JR., and MITCHEL BERNSTEIN (Introduced by Konrad Dobrinck), New York, N. Y.

The rate of total coproporphyrin excretion in the urine and feces has been observed in several patients receiving either the 8-day half-life radioactive isotope of iodine or x-radiation. In conjunction with this study complete hemograms including serial red-cell counts, hemoglobin, white-cell counts, platelet counts, bleeding and clotting time, bone-marrow biopsy, and liver function tests have been followed.

Three-day aliquots of urine and feces have been extracted for total coproporphyrin content according to the methods established by Dobrinck and Watson. The etiologues I and III of coproporphyrin are to be differentiated in a separate study.

It has been noted that there is an increase in total coproporphyrin excretion following radiation. This effect has been observed in patients receiving radioactive iodine

and x-radiation given in therapeutic doses, the largest single dose being 112 millicuries of I^{131} . The increased excretion has been reflected in both the urine and feces and has occurred ten to fourteen days following the onset of irradiation.

Concomitant with this increase in coproporphyrin excretion, a decrease in total lymphocyte count and a transient decrease in platelet count have been observed.

Granulomatous Polyarteritis: Report of a Case with Intra- and Extravascular Granulomas Combining Certain Morphological Features of Polyarteritis Nodosa and Acute Rheumatic Fever. J. P. KULKA, D. G. FREIMAN and W. S. CLARK (Introduced by William W. Beckman), New York, N. Y.

The relation between vascular and extravascular lesions is one of the major problems in the morphology of the rheumatic diseases. Of particular interest is the relation between the characteristic necrotizing angitis of polyarteritis nodosa and the Aschoff bodies and other extravascular granulomatous lesions of rheumatic fever. While both human autopsy studies and animal experiments seem to point to an intimate connection between these two disease manifestations, no direct evidence has yet been produced to indicate whether they are the result of the same or of different types of tissue injury.

Observations are therefore reported on a case of bronchial asthma and polyarteritis nodosa which at autopsy showed all transitional stages from classical segmental panarteritic lesions to miliary intramural granulomas on the one hand, and from extravascular miliary granulomas identical with those in the vessels to lesions indistinguishable from typical Aschoff bodies on the other. These findings strongly suggest that the segmental angitis and the focal granulomas are both produced by the same pathogenic mechanisms and provide additional evidence that polyarteritis nodosa and rheumatic fever may be expressions of the same fundamental disease process.

Effect of Rigid Na Restriction in Patients with Cirrhosis of the Liver and Ascites. HENRY G. KUNKEL, WILLIAM J. EISENMENGER and EDWARD H. AHRENS, JR. (Introduced by Thomas M. Rivers), New York, N. Y.

The intake of NaCl was limited to less than 1 gm. per day in 13 patients with steadily accumulating ascites. Fluid formation in the abdomen was immediately stopped in 12 of the 13 patients. The patients readily tolerated such a low salt diet for more than 3 months with the exception of one patient who showed an elevated NPN initially. As much as 150 gm. of protein per day could be consumed on this diet. The 12 patients who ceased to form fluid were markedly improved by the treatment, chiefly because the loss of body protein through paracentesis ended. This resulted in a rise in the serum albumin level. However, ascites reformed in all but 3 of the patients when the Na intake was raised to normal levels at the end of 3 months and longer periods of therapy were necessary for complete improvement. The critical level of NaCl intake where ascites formation began was ap-

proximately 1.3 gms. NaCl per day. Above this level the amount of ascites which formed was directly proportional to NaCl intake.

Detailed studies of nitrogen, Na and K balances were carried out in 3 of the patients before and after Na restriction. The patients were found to be in negative nitrogen balance prior to therapy chiefly because of the loss of ascitic fluid nitrogen. When this was stopped, they reverted to positive nitrogen balance. All the patients showed extremely low excretion of Na in urine prior to therapy and this was further reduced after the special diet was begun. Fecal Na levels were approximately 3 times the urinary values.

The conclusion drawn from these investigations is that rigid Na restriction is a valuable supplement to nutritional therapy for stopping the malignant downhill course of patients with rapidly accumulating ascites.

Studies of Water Storage in Liver Disease. II. The antidiuretic activity of the urine during acute infectious hepatitis. DANIEL H. LABBY (Introduced by Edwin E. Osgood), Portland, Ore.

In a previous study of 14 cases it was demonstrated that the acute phase of infectious hepatitis was marked by expansions of the thiocyanate fluid space, the plasma and blood volumes, depression of the plasma and urinary chlorides and increased water tolerance. Improvement in liver function with convalescence resulted in shrinkage of these fluid compartments and diuresis. Slight changes in total circulating proteins were detected. Eight additional cases of early hepatitis were selected to correlate the antidiuretic activity of the urine with the above fluid observations. 200 gm. male rats were given water (5 per cent of body weight) by stomach tube and injected intraperitoneally with 1 cc. of the patients dialized and concentrated urine per 100 grams of rat. The time required for the excretion of 50 per cent of the ingested water was taken as a standard assay end point; controls were run simultaneously by injecting water of the same pH intraperitoneally. The data obtained in each case indicate that in the early phase of acute infectious hepatitis at the time of maximum water storage and increased water tolerance the 50 per cent excretion time ranged from 155 to 360 minutes in comparison to control times of 80 to 110 minutes. With convalescence, contraction of the thiocyanate space, and diuresis, the antidiuretic titer of the urine decreased to control values. It is therefore concluded that the movements of body water occurring during acute infectious hepatitis are accompanied by alterations in the concentration of the antidiuretic principle in the urine; the potency of this principle being highest during periods of water storage in the acute stage and lowest during convalescence when excessive water storage is no longer demonstrable. Opportunity was also presented for conducting these studies during menstruation in the course of hepatitis and in a case of nonicteric hepatitis.

Evidence That Renal Sodium Excretion Is Controlled by Adrenal Cortical Activity and That Ingested Sodium May Displace Intracellular Potassium in Normal Sub-

jects. ALEXANDER LEAF (by invitation) and L. H. NEWBURGH, Ann Arbor, Mich.

The effects of great variation in sodium intake were studied in normal subjects maintained on fixed diets of adequate calories and protein with very low sodium and chloride content. At definite periods additional sodium was administered either as the chloride or citrate.

Salt restriction resulted in reduction in urinary sodium and chloride to minute amounts accompanied by increase in urinary nitrogen, urea, uric acid, potassium and phosphorus. Administration of sodium chloride or citrate caused high urine sodium with decrease in urine uric acid, potassium phosphorus, blood and urine urea, and positive nitrogen balance. The drop in blood urea was not accounted for by alteration in glomerular filtration rate but was explained by decrease in the rate of protein catabolism. A strongly positive potassium balance occurred simultaneously with the high sodium excretion that could not be accounted for by decreased protein catabolism.

All these changes are explained by alterations in adrenal cortical activity. The need to conserve body sodium was met by increased activity of the desoxycorticosterone-like hormone. An associated increase in protein-catabolic hormone activity was elicited also. Sodium administration abolished the need to conserve sodium and thus depressed adrenal cortical activity. This not only allowed a large urinary sodium excretion but also gave evidence of a marked decrease in activity of protein-catabolic hormone.

In all subjects sodium citrate administration caused initially a marked positive sodium balance. The degree of alkalosis was reduced by entry of large amounts of sodium into the cells with displacement of large amounts of potassium as evidenced by the strongly negative potassium balance.

Diagnosis of Carcinoma of the Liver, Biliary Tract, and Pancreas from Cytology of Duodenal Aspiration. H. M. LEMON and W. W. BYRNES (Introduced by James M. Faulkner), Boston, Mass.

The infrequency of successful surgical therapy for primary carcinoma of the liver, extra-hepatic bile ducts, and pancreas reflects in many cases clinical inability to establish an early positive diagnosis of cancer. In this study careful cytological examination has been made of aspirated duodenal contents in an effort to supplement currently available diagnostic methods. Although no previous studies have been reported concerning neoplastic cells in duodenal secretion, we have found that criteria accepted as indicating cancerous cell exfoliation from other epithelial surfaces can be readily applied to this fluid, since large numbers of tumor cells as well as normal epithelial cells have been observed in the majority of our specimens from patients with early or late cancer.

All cases have been followed for at least six months after examination or until death. Three-quarters of the cancer cases have been verified pathologically, and a close similarity in morphology has been found between the exfoliated cells and those in the pathological sections from the tumor. No false positive errors have been made, although control observations have been carried out in an equally

large number of cases of cirrhosis and inflammatory condition of the biliary tract and pancreas. Among the diagnosed cancers were hepatoma, primary cancers of the gall bladder, common bile duct, Ampulla of Vater, and the head and tail of the pancreas. Localized carcinomas as small as 2 cm. in diameter have been detected, as well as certain metastatic neoplasms. A brief description will be given of certain cases in which earlier diagnosis and institution of proper therapy have resulted from the application of this method to clinical problems with and without obstructive jaundice.

Acute Asphyxia in Dogs: Effects on Blood Coagulation and Citric Acid Metabolism. JESSICA H. LEWIS (Introduced by E. C. Hamblen), Chapel Hill, N. C.

These experiments were designed to study the effects of acute asphyxia on blood coagulation in dogs. The trachea was clamped in 13 anaesthetized dogs. Following the cessation of labored respiratory movements at about two and one-half minutes, the blood pressure fell, reaching zero at approximately six minutes. Two cc. arterial whole blood specimens were collected every fifteen seconds for the first two minutes and every five seconds thereafter. Markedly prolonged clotting times or incoagulable bloods were obtained during a 30-45 second interval occurring about 30 seconds after respirations had ceased. Both before and after this period blood coagulation times were normal.

Blood coagulation studies on the "incoagulable blood" showed normal (1) prothrombin complex, (2) fibrinogen, (3) platelets, (4) fibrinolytic enzyme system, and (5) antithrombin. No heparin or defect correctable by added thromboplastin could be detected.

The coagulation defect was readily reversed by the addition of calcium chloride. In spite of this, the total calcium concentration was normal. Therefore, we reasoned that calcium must be bound in some soluble, but non-ionized form.

Anaerobic carbohydrate metabolism may produce citric acid. Studies on four dogs have shown a rise of citric acid concentration from a normal value of approximately 75 micrograms/cc. to 1,000 micrograms/cc. in the "incoagulable blood" followed by a fall to normal values at death. Aconitic acid did not change appreciably. Parallel studies with added sodium citrate showed that 900 micrograms/cc. (as citric acid) were sufficient to prevent coagulation.

Acute asphyxia in the dog produces a marked rise in blood citric acid content, sufficient to bind ionized calcium, and so far as we are aware, this is the first reported incidence of calcium ion deficiency resulting in a blood coagulation defect. An adequate explanation for the extremely temporary but marked elevation in blood citric acid is being sought.

Studies in Urinary Corticosteroids by a Method Permitting Analysis of Desoxycorticosterone. CHARLES W. LLOYD and JULIA LOBOSKY (Introduced by Eugene L. Lozner), Syracuse, N. Y.

The method of Daughaday, Jaffe and Williams for estimation of freely water soluble urinary corticosteroids has been modified to permit analysis of the poorly water soluble corticosteroids, such as desoxycorticosterone.

Excretion of corticosteroids by normal individuals and by six patients with Addison's disease has been studied by this method. Low corticosteroid values were found in all patients without treatment. Following beginning of desoxycorticosterone acetate injections, there was a latent period of several days before the excretory rate began to rise. In one patient with a fixed daily dose of 5 milligrams of desoxycorticosterone there was a gradual increase in corticosteroid excretion over a period of a month. Following complete withdrawal of desoxycorticosterone, excretion continued at a high level for approximately 96 hours before a significant decrease was observed. In one patient, clinical evidence of adrenal insufficiency appeared within one day of this decrease. The excretion rate of corticosteroid was in the middle of the normal range when the desoxycorticosterone dose was at the optimal level as determined by clinical response. Excessive dosage was associated with higher corticosteroid values, which, however, did not exceed the normal range. Following implantation of pellets, with good clinical control, excretion of corticosteroid was lower than when desoxycorticosterone in oil was injected in amounts sufficient to produce a comparable clinical effect.

One patient with Addison's disease when untreated had a corticosteroid excretion only slightly below the normal range. Administration of desoxycorticosterone produced relatively small increases of urinary corticosteroids. Withdrawal of desoxycorticosterone was followed by the very slow appearance of symptoms of insufficiency. It is believed that this patient has viable adrenal tissue which is capable of secretion, although at an inadequate rate, and it is suggested that when desoxycorticosterone was administered, this secretion was depressed.

Studies in Hemoglobin Formation with the Aid of the Isotope Technique. IRVING M. LONDON, DAVID SHEMIN and D. RITTENBERG (Introduced by Randolph West), New York, N. Y.

When the whole blood of patients with sickle cell anemia is incubated *in vitro* with glycine labeled with N^{15} , heme containing N^{15} is formed. This finding demonstrates *in vitro* synthesis of heme. No significant synthesis is found on incubation of normal human blood. To help determine whether the immature reticulocyte or the mature pathologic cell of sickle cell anemia is responsible for the synthesis, studies have been carried out in a variety of hematologic disorders characterized by elevated reticulocyte counts (pernicious anemia, congenital hemolytic jaundice, acquired hemolytic anemia) and in experimental animals in whom reticulocytosis was induced by bleeding or phenylhydrazine hemolysis. These studies indicate that some, though perhaps not all, reticulocytes are capable of synthesizing heme *in vitro*. The differences in capacity for heme synthesis manifested by reticulocytes of various sources will be discussed.

The incubation of N^{15} labeled glycine and other isotopic

compounds with blood containing numerous reticulocytes affords a method for the study of heme formation. Avian nucleated red blood cells may be used similarly. Studies concerned with the optimal conditions for *in vitro* heme synthesis, with the use of the *in vitro* systems for the determination of the biologic precursors of protoporphyrin, and with some of the mechanisms involved in heme formation will be discussed.

Experimental Airborne Influenza Virus A Infection in Immunized Animals. CLAYTON G. LOOSLI and (by invitation) ROBERT S. ROCKWALD and MERLE H. RITTER, Chicago, Ill.

Young adult Swiss mice (10-15 grams) were immunized by 4 weekly 0.1 ml. subcutaneous injections of formalized mouse lung suspension (10-1 dilution) of PR-8 strain of Influenza A virus. Neutralization and CRC agglutinin-inhibition tests were employed for antibody determinations on pooled sera. Immunized and nonimmunized mice of similar age were exposed in a chamber at the same time to a lethal atmosphere of nebulized mouse lung PR-8 virus suspension. Five mice from each group (2 for histology and 3 for virus and antibody titration) were bled and killed at close intervals until death or 16 days after inoculation. Additional animals served to determine survival rates.

In the non-immunized animals, the influenza infection was rapidly fatal with death occurring on or before the fifth day. The lungs at death showed extensive consolidation with marked destruction of the bronchial epithelium and extensive edematous and cellular exudate in the alveoli. The immunized animals became moderately ill but survived. Grossly, only focal areas of consolidation occurred, which underwent resolution after 8 days. Microscopically, as in the control lungs, there was extensive destruction of the bronchial epithelial cells but the alveolar exudate was patchy and generally confined to regions near the terminal bronchioles. Also, as in the non-immunized animals, the virus grew rapidly in the lungs of the immunized animals, reaching a titer of over 10^6 lethal intranasal doses at 36 and 48 hours. At this time, the serum antibody level of 1:512 before infection had dropped to the non-immune level of < 1:16. At 6 days, only traces of virus were present and the antibody titer had risen several fold above the original immune level. The mechanism of protection against influenza virus in the immunized animals and in man in relation to the above observations will be discussed.

Spirocheticidal Antibodies in Syphilis. HAROLD J. MAGNUSON and (by invitation) FRED A. THOMPSON, Chapel Hill, N. C.

The *in vitro* technic described by Nelson, employing the Nichols strain of *T. pallidum*, permits demonstration of a spirocheticidal substance found in most syphilitic sera from humans and rabbits but not present in normal sera. Electrophoretic fractionation of such sera shows the activity to be associated with the gamma globulin. The substance is found in Fraction II-III of Cohn, is relatively

heat stable, and requires complement for its demonstration. This evidence suggests that the substance is an antibody.

The antibody is not related to reagin since its presence bears no relation to the titer of serologic tests for syphilis. Sera from which reagin has been absorbed retain their activity, and the purified reagin recovered from the precipitate is inactive. Assays are reported on sera from 200 patients with syphilis in various stages as well as from rabbits with known varying degrees of immunity. The possible relationship of this antibody to acquired immunity is discussed.

The Production of Renal Glomerular Lesions in the Diabetic Rat. GEORGE V. MANN and JAMES W. GODDARD (Introduced by Howard F. Root), Boston, Mass.

Weanling male rats have been made diabetic by the intravenous injection of alloxan monohydrate. A total of 50 animals have been maintained on one of 4 diets up to 550 days. The diets were dog chow and semipurified diets containing 12, 18 and 40 per cent protein. No insulin was given. At intervals animals were sacrificed and tissues examined.

It has been found that diabetic rats develop well marked progressive lesions in the renal glomeruli as early as 50-90 days. The lesions primarily affect the reticulin walls of the glomerular capillary tufts, parietal layer of Bowman's capsule and tubular basement membranes.

Reticulin proliferation produces intercapillary adhesions and luminal obliteration. The latter process may occur either by collapse reticulosis or by luminal ingrowth of reticulin fibers. In some instances hyaline-like balls are entrapped in the inter-capillary and axial spaces. Reticulin overgrowth in a meshwork pattern leads to ball formation, reminiscent of the fibrous balls of human nephrosclerosis. The parietal layer of Bowman's capsule shows irregular thickening and collagenization. Tubular basement membranes show thickening with hyaline changes.

Especially in old diabetic animals an increased cellularity of the glomerular tufts appears due to a remarkable hyperplasia and hypertrophy of what appear as perithelial cells.

These lesions have not been found in nondiabetic control rates or in nondiabetic alloxan injected controls. No lesions have been found in the aorta and its branches. Renal arteriolar lesions have been minimal. Neither the severity of diabetes nor the level of protein in the diet has been shown to influence these manifestations.

Mechanism of the Depressor Effect of Accelerated Sodium Depletion in Hypertension. R. S. MCGROW, J. J. BOORMAN, J. SIROTA and H. POLLACK, New York, N. Y.

We have shown that the depressor response developing in hypertensive patients on low sodium diets may be accelerated materially by increasing the rate of sodium depletion through the use of mercurial diuretics.

The following studies were undertaken in order to elucidate the more fundamental relationships involved:

A: Adrenocortical function was investigated from determinations of the 17 keto and 11 oxy corticosteroids.

from glucose tolerance tests, from the blood uric acid, and from the eosinophile and lymphocyte response.

B: The effects of sodium depletion upon glomerular and tubular function and upon renal blood flow were determined by measuring the para-amino-hippurate and the mannitol or inulin clearances.

C: Using the T-1824 method, the possible role of decreased circulating blood volume in the depressor response to sodium depletion was studied.

D: The time relationships between sodium depletion and the depressor response were clarified by measuring the daily 24-hour sodium excretion by the flame photometer method.

E: Alterations in vascular reactivity were evaluated microplethysmographically, by contrasting the vasodilator responses to tetraethylammonium and dihydroergocornine before and after accelerated sodium depletion.

The evidence suggests that the decline in blood pressure which follows accelerated sodium depletion is associated with a temporary alteration of corticoid function. The conclusions drawn from the above investigations will be illustrated and discussed more completely.

Clinical Studies on the Pure Veratrum Alkaloids Protoveratrine and Veratridine. EDWARD MEILMAN and OTTO KRAYER (Introduced by S. L. Gargill), Boston, Mass.

The vasodepressor and cardiodecelerator action of *protoveratrine* hydrochloride has been studied for the first time in human renal and essential hypertension. It was administered intravenously, eighty times in fifteen patients, in single doses of between 0.08 mg. and 0.18 mg.

The characteristic response is a fall of systolic and diastolic blood pressure reaching minimum level within ten minutes. Intensity of effect is roughly proportional to the dose, varying between a significant decrease and a blood pressure fall to normal levels. Duration of action, likewise, is proportional to the dose, return to hypertensive levels occurring between fifteen minutes and three hours. Repeated administration of the same effective dose, in the same patient, leads to similar responses after the previous effect has worn off.

The vasodepressor action is accompanied by bradycardia, usually with regular sinus rhythm. Occasionally, the largest doses shifted the pacemaker, the ventricle beating faster than the auricle.

Atropine reduces but does not abolish the vasodepressor effect, while it increases the heart rate above normal and restores regular sinus rhythm. Simultaneous administration of *protoveratrine* and atropine causes a vasodepressor effect with a concomitant increase in heart rate.

Apart from the disturbance of rhythm, a slight and transient feeling of nausea occurred a few times.

Veratridine has circulatory effects qualitatively similar to those of *protoveratrine* but is less potent. With *veratridine* significant vasodepressor action cannot be obtained without side effects like nausea, vomiting, sweating, and feeling of apprehension. Occasionally, these occurred with doses not decreasing blood pressure.

Their unique mechanism of action makes the *Veratrum* alkaloids important substances for careful clinical studies in hypertension. For satisfactory clinical use the search must be directed towards pure alkaloids pharmacologically similar to *protoveratrine*, with a margin of safety and an intensity and duration of vasodepressor action equal or possibly superior to that of *protoveratrine*.

The Determination of Maximum Composite Digital Vascular Caliber Physiologically in Normal and Hypertensive Subjects. MILTON MENDLOWITZ, New York, N. Y.

In animal perfusion experiments with Ringer's solution the pressure-flow relationship has been demonstrated to be rectilinear. For blood this relationship has been found to be logarithmic. That portion of the curve above flow readings of one-third the "normal," however, corresponds closely to a rectilinear tangent with an intercept on the pressure coordinate above zero.

The pressure-flow relationship in the human digital circulation after release of sympathetic tone was studied at various pressure levels achieved by graded compression of the brachial artery. This relationship corresponded well with a rectilinear tangent both in normotensive and hypertensive subjects. The intercepts were similar to those observed in animal experiments.

The "apparent viscosity" of normal blood at a "normal" perfusion pressure has been shown in animals to be 2.2 times that of Ringer's solution. There is reason to believe that this holds for the human digital circulation. If the intercepts are known, it is possible to draw a pressure-flow tangent from a single pressure-flow reading. At the point of "normal" pressure a theoretical Ringer's solution perfusion point can be erected and the Ringer's solution pressure-flow line drawn to the intercept zero. Poiseuille's law is now applicable, the only unknown quantities being length and caliber of the perfused vessels. Since the flow is measured per sq. cm. of skin, the average length of the perfused vessels can be estimated at 1.1 cm. The composite digital vascular caliber of a single vessel, the resistance of which is equal to that of all the vessels per sq. cm. of skin perfused can be computed. It was found to vary from 67 to 75 micra normally and to be below normal in hypertension.

Clinical Experience with the Use of an Artificial Kidney. J. P. MERRILL (by invitation), G. W. THORN, and (by invitation) E. J. CALLAHAN and S. SMITH, Boston, Mass.

A modification of the Kolff type of artificial kidney has been used in 28 cases in 18 patients with uremia. Difficulties encountered by previous observers with hemolysis, clotting and pyrogen reactions have been virtually eliminated. Adjustment of the tonicity of the bath fluid to the patient's serum by means of freezing point determinations has so greatly increased the accuracy with which hydration may be controlled that it is feasible to employ the procedure in uremic patients with congestive failure and even pulmonary edema. The adjustment and balance of blood flow rates through the machine have further de-

creased its risk in application to patients with cardiovascular disease.

The effectiveness of this machine in removing diffusible substances from the blood by in vivo continuous dialysis is indicated by the fact that with blood flow rates between 200 and 300 cc. per minute and blood urea nitrogen level of 80 to 90 mg. per 100 cc., it is possible to remove 20 grams of urea per hour with comparable quantities of other retained metabolites. The machine may also be employed to remove specific ions by dialysis and three instances of acute spontaneous potassium intoxication have been successfully treated by the removal of excess potassium from the blood stream. The possibility of removing specifically other diffusible substances, including sodium, uric acid, water and amino acids is under investigation. It is concluded that the present technique of application of an artificial kidney is an effective and clinically safe procedure for the removal of diffusible substances by continuous dialysis of the blood. The value of its use as a means of therapy in acute renal failure and in a variety of forms of intoxication is well established. Its use as an investigative tool in the study of chronic cardiovascular and renal diseases is apparently warranted.

Treatment of Pernicious Anemia with an Animal Protein Factor of Bacterial Origin. LEO M. MEYER, NORTON D. RITZ, MANUEL ROWEN, GEORGE BOCK and JULIUS RUTZKY (Introduced by Arthur C. De Graff), New York, N. Y.

An animal protein factor concentrate was prepared from the aerobic fermentation of a non-motile gram negative bacillus isolated from chicken feces. One cc. of this product (A.P.F. 60) had a biologic activity equal to "10 unit liver" when administered to chicks receiving a diet containing 70 per cent soy bean meal. In the lactobacillus assay the material had a somewhat lower potency (65 per cent of "10 unit liver"). A more concentrated preparation (Normocytin) had a potency comparable to 10 micrograms of vitamin B 12 when administered to chicks maintained on a diet containing 70 per cent soy bean meal. Administration of A.P.F. 60 to 5 patients with pernicious anemia in relapse induced a satisfactory reticulocyte response in 4 instances, with an increase of Hb and R.B.C. in all cases. Eight other persons with pernicious anemia in relapse treated with Normocytin showed a satisfactory reticulocytosis. An increase of Hb and R.B.C. to normal levels occurred in 6 cases. One patient from the original group treated with A.P.F. 60 was continued on Normocytin and also reached normal hematologic values. In all instances there was improvement in appetite and general well-being of the patients. Megaloblastic bone marrows were converted to normal states. Where neurological changes were present improvement was noted. There was no instance of progression or development of nervous system signs or symptoms. In two patients the Hb and R.B.C. remained below normal levels and are at present under treatment with vitamin B 12.

Effect of Urethane on the Susceptibility of Mice to Pneumonia Virus of Mice (PVM). GEORGE S. MIZICK,

CHARLES I. LEFTWICH, JR. and WILLIAM B. LEFTWICH (Introduced by Paul W. Clough), Baltimore, Md.

The effect of urethane on the susceptibility of the young mouse to infection by pneumonia virus of mice (PVM) was tested. This compound seemed of interest because of its reported suppressive action on cell growth and its capacity to induce pulmonary tumors in older mice of certain strains.

Suitable matched groups of young mice were lightly anesthetized with ether, and inoculated intranasally with serial ten-fold dilutions of PVM. All groups were fed Purina Dog Chow and each was given to drink either water or water containing various concentrations of urethane. It was observed repeatedly that drinking 0.1 per cent or more urethane during the post-inoculation period rendered mice 5 to 10 times more susceptible to this virus infection than controls. A single intraperitoneal injection of urethane before virus inoculation produced similar effects.

Some possible mechanisms for urethane's action in increasing the mouse's susceptibility to PVM were studied. Mice given urethane orally gained less weight and drank less fluid than controls. However, limiting food or fluid in other mice did not reproduce the effect of urethane. Moreover, one injection of 5 mg. of urethane before inoculation increased susceptibility ten-fold without affecting the weight curve. Other cell growth depressants like colchicine and podophyllotoxin did not have effects like that of urethane on susceptibility to the virus infection.

Insulin Tolerance Test in Patients with Essential Hypertension. I. ARTHUR MIRSKY, (by invitation) STANLEY M. KAPLAN and R. H. BROTH-KAHN, Cincinnati, Ohio.

The blood sugar response to the intravenous injection of a standard dose of insulin is dependent upon factors which affect the hypoglycemic action of insulin and factors which affect the restitution of the blood sugar to the pre-injection level. Some of the hormones of the anterior pituitary gland and the adrenal cortex are among the factors which determine the effectiveness of the hypoglycemic action of insulin whereas the activity of the sympathico-adrenal system largely determines the rate of restitution of the blood sugar concentration to the preinjection level. Since both sets of factors have been implicated in the genesis and maintenance of the hypertension of patients with essential hypertension, we deemed it pertinent to study the insulin tolerance of such patients.

Blood samples were drawn for sugar determination before, and at 15, 30, 45, 60, 90 and 120 minutes after the intravenous injection of 0.1 unit insulin per kilogram body weight to fasting normotensive and hypertensive subjects. The carbohydrate stores of all subjects were fortified by ingestion of two grams of carbohydrate per kilogram body weight after the usual meal the night before the test.

The hypoglycemic response of both groups of subjects was not statistically different. However, statistical analysis of the data revealed that the rate of restitution of

the blood sugar concentration to the preinjection level was markedly delayed in the hypertensive group.

These studies indicate that there is no significant increase in contra-insulin factors in patients with essential hypertension. Further, if the rate of restitution of the blood sugar concentration is dependent upon the degree of activity of the sympathico-adrenal system, then the response of this system to hypoglycemia must be reduced in the hypertensive group.

The Destructive Effects of the Virus of Russian Far East Encephalitis on the Transplantable Mouse Sarcoma 180.

ALICE E. MOORE (Introduced by C. P. Rhoads), New York, N. Y.

A study was made of the ability of certain viruses to grow in transplantable mouse tumors and to determine what effect their growth would have on the viability of the tumor. The virus of Russian Far East Encephalitis was found to have a marked affinity for the transplantable mouse Sarcoma 180 and in the process of viral infection the viability of the tumor was completely destroyed. When subinfective amounts of virus were inoculated there was no effect on tumor growth and no virus could be recovered from the tumor or brain.

Following intraperitoneal inoculation of 0.05 cc. of $10^{7.5}$ brain virus suspension, tumors were removed for bioassay and the amount of virus present in the blood, brain and tumor was determined. For the first five days more virus was present in the tumor than in either blood or brain. From the 5th day until the death of the animals approximately equally large amounts of virus were present in the tumor and brain while it disappeared from the blood. Portions of the tumors were implanted into virus-immune and non-immune control mice at different days after intraperitoneal inoculation. In all cases in which implantations were made into non-immune mice no tumor growth was apparent and the animals died of virus infection in 1 to 2 weeks. When pieces of these same tumors were implanted into virus-immune mice it could be demonstrated that although the virus was present in large amounts three days after intraperitoneal inoculation an additional 3 or 4 days exposure in the intact animals was necessary before all the tumor cells were killed.

Tolerance to the Toxic Effects of Somatic Antigens of Enteric Bacilli in Typhoid and Paratyphoid Fever Convalescents. HERBERT R. MORGAN and (by invitation) FRANKLIN A. NEVA, Ann Arbor, Mich.

The somatic or O antigen (endotoxin) of *Salmonella typhosa* is the component responsible for toxicity of this organism and is a major determinant of its antigenic properties. When injected intravenously in man in minute doses, the endotoxin produces chills, fever, headache, muscle aching and generalized malaise and in some instances nausea and vomiting. Since there is evidence that the somatic antigen of *S. typhosa* is present in the blood during the acute phase of typhoid fever, it has been suggested that this toxic component might be responsible for certain of the clinical manifestations of the disease.

Following repeated intravenous injections of typhoid somatic antigen, individuals develop a resistance to its toxic effects which is not dependent on the presence of circulating O antibody which also appears. This tolerance is also protective against the similar toxic manifestations of the serologically unrelated antigen of *Shigella dysenteriae* for which no O antibodies are present.

Patients convalescent from typhoid and paratyphoid fevers and certain other infectious, febrile diseases were tested for resistance to the toxic effects of somatic antigens of *S. typhosa* and *Sh. dysenteriae*. Twenty-five of thirty-one patients convalescent from typhoid fever and eighteen of twenty-one patients convalescent from paratyphoid fever showed no significant reactions to intravenous test doses of the endotoxin of *S. typhosa* (5 γ) and *Sh. dysenteriae* (1 γ) which produce marked febrile responses and systemic reactions in normal individuals.

When retested four to six months later, eight of eleven of these patients were shown to be resistant. In the three patients who were susceptible to the initial test dose, four test injections showed that the tolerance to the toxic effects of the somatic antigens was rapidly reestablished.

Five patients, who were convalescent from other febrile infectious diseases, developed fever and systemic reactions which were comparable to those seen in normal subjects following the injection of test doses of somatic antigens.

The implications of these findings in relation to recovery from typhoid and paratyphoid fever will be discussed.

Plasma Volume, Red Cell Volume and "Extravascular Thiocyanate Space" Changes in Patients on Rice Diet. RICHARD J. F. MURPHY (Introduced by Julian M. Ruffin), Durham, N. C.

Serial observations of the plasma volume, "extravascular thiocyanate space" and red cell volume of 19 patients on the Kempner rice diet have been made. Period of observation was 14 weeks; measurements were made before starting the diet and at 3, 6, 10, and 14 week intervals following.

Seventeen patients had hypertensive disease of different types and 2 had coronary artery disease without hypertension. None had cardiac failure nor azotemia. Eleven had some alteration in renal function as measured by urinalysis, P.S.P. excretion and concentration test.

Plasma volume was measured by T1824 dilution and red cell volume was calculated from venous hematocrit.

Sixteen of the 19 patients showed significant loss of plasma volume. Mean loss in these patients was 14 per cent. This occurred chiefly during the first 6 weeks, the volume remaining relatively constant during the following 8 weeks observation.

In general loss of "extravascular thiocyanate fluid" followed the same pattern. The mean loss in this volume was 15 per cent.

Decrease in red cell volume was a constant finding in all 19 cases and showed no simple relation to fluid loss. The mean loss was 24 per cent. This could not be accounted for by blood loss from venesection for study purposes. In those cases with plasma loss only one-third

of this was reflected in the hematocrit, the other two-thirds being masked.

Weight loss was a prominent finding in some cases. There was no close correlation between weight loss and fluid loss either of degree or in time relationships. Although fluid loss was greatest in those with evident renal damage, 7 of the 8 patients with normal renal findings showed significant loss. There were no cases of frank clinical salt depletion.

There was no simple relationship between volume changes and clinical course.

Observations on the Excretion of Bromsulphalein. J. D. MYERS (Introduced by Keith S. Grimson), Durham, N. C.

Two important factors in the excretion of bromsulphalein by the liver are (a) amount of dye presented to the liver per unit of time, i.e. hepatic plasma flow, and (b) ability of hepatic cells to extract and excrete dye. Some evidence concerning the operation of these factors in normal and diseased states has been collected while measuring hepatic blood flows. Pertinent data are the arterial concentrations of BSP resulting from various dosages of dye, and the percent extraction of dye by the liver. Since the corrected infusion rate of BSP can be assumed equal to hepatic excretory rate, the data allow calculation of the BSP clearance

$$\frac{\text{infusion (excretion) rate}}{\text{arterial concentration}}$$

as ml. of plasma cleared completely of dye per minute per sq. M. Mean BSP clearance in 39 control subjects was 244 ± 83 ml.; mean per cent extraction was 53.2 ± 13.7 .

In 8 patients with severe, chronic anemia the increased hepatic plasma flow, due both to increased whole blood flow and lowered hematocrit, provided a normal if not supernormal clearance (277 ± 135 ml.) in the presence of decreased per cent extraction (30.7 ± 13.7). In 19 patients with cardiac failure, and low cardiac outputs and hepatic blood flows, the decreased clearance (89 ± 43 ml.) was due to both decreased supply of dye to the liver and impairment in hepato-cellular function (mean per cent extraction 28.5 ± 11.5). Nine individuals with Laennec's cirrhosis of moderate severity who had normal or moderately subnormal blood flows, had a markedly reduced mean clearance (134 ± 41 ml.) due largely to decreased extraction (32.8 ± 15.6 per cent). In 16 patients with hyperthyroidism mean clearance (212 ± 97 ml.) and per cent extraction (37.2 ± 17.6) were not significantly different from control values, although 6 of the group did have subnormal extraction percentages and presumably hepato-cellular dysfunction.

In both controls and ill patients, simultaneous infusion of bilirubin, human albumin, or amino-acids with bromsulphalein impaired excretion of BSP by decreasing per cent extraction.

Incidence and Nature of Hepatic Disturbance Following Acute Viral Hepatitis and in Persons with Maximal and Minimal Exposure to Hepatitis Virus: A Preliminary Report.

J. R. NEEFE and (by invitation) HUGO DUNLAP SMITH, CHARLES H. KURTZ, LEWIS WILLIAM BLUEMLE, JR., S. CLAY WILLIAMS and JOHN G. REINHOLD, Philadelphia, Pa.

The incidence and nature of hepatic disturbance has been investigated in: Group IA: 300 persons chosen at random from records containing sufficient information to justify a diagnosis of acute viral hepatitis 2 to 7 years previously; Group II (Maximal Exposure Group): 158 persons chosen at random from records indicating unusual exposure to hepatitis virus during the preceding 7 years; Group III (Minimal Exposure Group): 120 persons selected because of the lack of any recognized unusual exposure to hepatitis virus. Group IB is composed of selected patients with moderately severe symptoms and disability following acute viral hepatitis. The study of each person included a detailed history, a complete physical examination, a comprehensive group of hepatic tests, and, in representative cases, needle biopsies of the liver. An unexpectedly high incidence of findings suggesting mild hepatic disturbance has been encountered in both the maximal and minimal exposure groups. The incidence of such findings to date in the unselected post-hepatitis group (IA) has been only slightly higher. The observations on the selected post-hepatitis group (IB) support existing evidence of the occasional occurrence of a severe form of chronic liver disease with diffuse hepatic fibrosis following acute viral hepatitis. The data from the 3 "unselected" groups indicate that such major sequelae are infrequent but reveal the existence of a relatively large number of persons in all 3 groups with evidence of chronic mild hepatic disturbance which may be related to preceding apparent or inapparent infection with hepatitis virus.

Studies on Treponemal Immobilizing Antibodies Produced in Syphilitic Infection. ROBERT A. NELSON, JR., JUDITH A. DIESENDRUCK and HAROLD E. C. ZHEUTLIN (Introduced by Thomas B. Turner), Baltimore, Md.

A method has been developed by which antibodies to virulent *Treponema pallidum* can be demonstrated *in vitro*. Treponemes are extracted from rabbit testicular syphilomas and suspended in a special medium in which the organisms remain motile and infective for several days. On incubation of such suspensions with syphilitic rabbit or human sera and guinea pig complement, the treponemes become non-motile and lose their capacity to infect rabbits. This immobilizing activity is virtually absent from normal serum.

Using this technique, a preliminary survey of serum and cerebrospinal fluid from patients in various stages of syphilis has been made. Of 20 sera from patients with primary syphilis, 10 produced marked immobilization, three were doubtful, and seven showed no immobilizing effect. All sera from 20 patients with secondary syphilis, 15 with symptomatic tertiary syphilis, and two with congenital syphilis were strongly positive. All sera from 20 presumably normal individuals, and 20 patients with diseases other than syphilis were negative.

Similarly, cerebrospinal fluids from 10 patients with central nervous system syphilis were positive while fluids from 10 non-syphilitic patients were negative.

By absorption experiments it has been demonstrated that the immobilizing antibody is distinct from reagin which is detected by the ordinary serological tests for syphilis. Thus far, the sera of seven patients with unquestionable biological false-positive serological reactions were completely negative with the treponemal immobilization test.

Since the immobilizing antibody appears to be directed specifically against *T. pallidum*, it may afford a practical method for the study of the immunology of syphilis in man.

The Effects of Salt-Poor Albumin on the Excretion of Water and Electrolytes in Edematous Patients. JACK ORLOFF, LOUIS G. WELT and LYMAN STOWE (Introduced by Paul H. Lavietes), New Haven, Conn.

The infusion of 100 grams of a 25 per cent solution of salt-poor albumin may initiate a diuresis of water and sodium in edematous patients. When albumin is administered to normal subjects, however, despite similar hemodynamic changes, the excretion of sodium is decreased and that of water not significantly altered.

Albumin was injected intravenously as a 25 per cent solution into 2 patients with toxemia of pregnancy, 3 with the nephrotic syndrome, an edematous pregnant female without toxemia and 2 normal subjects. In those patients in whom the sequence of events were analyzed, there was initially a profuse water diuresis in which water was lost far in excess of sodium. The resultant elevation of the concentration of sodium in the extracellular fluid was associated with a diuresis of salt.

In contrast, in both normal individuals and in edematous patients who did not develop a water diuresis during the infusion of albumin, there was no change in the level of sodium in the extracellular water, and no subsequent increase in the excretion of salt.

From these studies it appears that the primary diuretic action of albumin in some edematous patients is to promote a diuresis of water. If water is lost sufficiently in excess of salt to elevate the concentration of sodium in the extracellular compartment, an increased excretion of sodium ensues.

Observations on Experimental Pulmonary Edema. ROBERT PAINE (by invitation) and JOHN R. SMITH, St. Louis, Mo.

Experimental heart failure in dogs with intact circulation usually causes no pulmonary edema, although pulmonary congestion may be marked. In contrast, heart-lung preparations always develop "spontaneous" pulmonary edema, in time. These phenomena were investigated in dogs. In all instances pulmonary lymph flow was measured by modifications of Drinker's technique.

In eight experiments, congestion of individual lung lobes, or of the entire lungs, produced no increase in lymph flow nor evidence of pulmonary edema.

The role of decreased plasma proteins in lung edema was investigated in nine experiments. Sufficient intravenous Locke's solution was infused to reduce the plasma proteins to about 2.6 grams per cent. Marked and sustained pulmonary lymph flow occurred, although systemic venous pressure was little influenced by the infusions. In addition, complete mechanical obstruction of the pulmonary lymphatic duct provoked no evident gross pulmonary edema; however, in the same animals Locke's infusion again resulted in lung edema.

Heart-lung preparations were set up, following isolation of the right lymphatic duct. Pulmonary lymph flow increased immediately after establishment of the heart-lung circuit (five experiments). In eleven other instances, lymph flow was carefully measured as various vessels were tied off in making heart-lung preparations. Thus, heart-lung-head preparations could be established in which the lung lymph flow was *not* increased. However, when the cephalic arteries were ligated (making an ordinary heart-lung), augmented lymph flow and eventual pulmonary edema occurred. Possibly autonomic effects from cerebral ischemia may influence the development of pulmonary edema when the heart-lung-head is transformed to the heart-lung circuit. Other evidence suggests that the rapidity of onset of pulmonary edema in the heart-lung is intensified when left ventricular overloading occurs, producing elevation of both pulmonary arterial and venous pressures, and consequent destructive rise in capillary pressure.

An Abnormality in Nitrogen Metabolism in Cushing's Syndrome Altered by Testosterone Propionate: A Study Utilizing Glycine Tagged with Isotopic Nitrogen, N 15. WILLIAM PARSON (Introduced by Thomas Findley), New Orleans, La.

Isotopic nitrogen, N 15, was incorporated in glycine and fed in single small doses to healthy men on normal and high protein diets. The rates of urinary excretion of N 15 were determined by the use of the mass spectrometer. Simultaneous nitrogen balances were made. Our results are similar to the observations of the Columbia group, reported in part by Sprinson. Approximately 30 per cent of the fed N 15 appears in the urine in 24 hours when the diet contains 1 gram of protein per kilogram of body weight. The rate increases to approximately 45 per cent on a high protein diet containing 1.5 grams of protein per kilogram.

A patient with Cushing's Syndrome in nitrogen equilibrium and maintaining her weight on a diet containing 1 gram of protein per kilogram, was given "tagged glycine" as above. N 15 excretion rates were determined. The observations were repeated during a period of nitrogen retention induced by testosterone propionate. Control observations were again made when nitrogen equilibrium returned after cessation of therapy.

In this patient, at the end of 24 hours, approximately 45 per cent of the fed N 15 appeared in the urine during both control periods. This figure fell to approximately 30 per cent during testosterone administration.

The significance of this abnormality in nitrogen metabolism is not established. If the assumption is made that "tagged glycine" traces "protein metabolism," analysis of the data suggests that the abnormality in this case of Cushing's Disease may represent "decreased protein anabolism," altered toward normal by testosterone propionate.

Cerebral Blood Flow and Oxygen Consumption in Neurosyphilis. JOHN L. PATTERSON, JR., ALBERT HEYMAN and FENWICK T. NICHOLS, JR. (Introduced by Paul B. Beeson), Atlanta, Ga.

The cerebral blood flow was determined by the nitrous oxide technique of Kety and Schmidt in 48 patients with neurosyphilis and 12 control subjects. Cerebral oxygen consumption was calculated from the flow data and the arteriovenous oxygen difference.

In patients with paresis and meningovascular syphilis the cerebral blood flow was below the normal mean in almost every instance. The mean cerebral blood flow in these conditions was 75 per cent and the lowest 32 per cent of the normal mean. The cerebral oxygen consumption was reduced in both groups, but a more marked reduction was found in the patients with paresis. In these patients the average oxygen consumption was approximately 70 per cent of the normal with an extreme value of only 24 per cent of the normal. In patients with asymptomatic neurosyphilis, both the blood flow and oxygen consumption were within the normal range.

The effect of penicillin and malarial fever therapy was studied in 17 of the patients. The mean cerebral blood flow one to six months following treatment in paresis showed no consistent change, while the oxygen consumption showed a marked mean increase (35 per cent). These changes could be correlated to a considerable degree with improvement in the patients' mental status. In most of these patients the improvement in cerebral oxygen consumption was proportionately greater than the increase in blood flow. In meningovascular syphilis the mean cerebral blood flow following therapy increased by an average of 20 per cent of its pre-treatment value, while the oxygen consumption showed only a small increase. In several patients with either paresis or meningovascular syphilis the improvement in cerebral blood flow was associated with an actual decrease in oxygen consumption or vice versa.

These studies suggest that the syphilitic process can exert a direct effect on cellular metabolism in the brain in addition to impairing its blood supply.

Postoperative Alkalosis and Potassium Deficiency. O. H. PEARSON and L. P. ELIEL (Introduced by Rulon W. Rawson), New York, N. Y.

A syndrome characterized by alkalosis, hypochloremia, and hyponatremia has been observed in 15 patients undergoing major surgery and being maintained by intravenous feeding for several days postoperatively. Clinically these patients exhibited muscular weakness, drowsiness, nausea, abdominal distention, and cardiac irregu-

larities. Electrocardiographic changes occurred, such as depression of T waves, prolongation of the QT interval, depression of ST segments, inversion of P waves, frequent extrasystoles and auriculo-ventricular block. Administration of potassium chloride intravenously or by mouth resulted in clinical improvement, a return to normal of the acid-base and electrolyte disturbance, and disappearance of the electrocardiographic abnormalities.

These electrolyte disturbances show a striking resemblance to those observed in certain patients with Cushing's syndrome. Darrow has observed similar electrolyte changes in rats that were made potassium deficient by several different methods. We have observed the development of alkalosis and potassium deficiency in a patient treated with adrenocorticotrophic hormone. The data will be presented.

These results suggest that the pathogenesis of this syndrome in postoperative patients is due to the alarm reaction producing hyper-function of the adrenal cortex, with loss of potassium and chloride (or retention of sodium) in the urine, associated with a low intake of potassium. Other factors which may contribute to the loss of potassium and chloride will be discussed.

A Statistical Analysis of the Physiological Factors Determining Cardiac Output in Normal Subjects. RAYMOND PEARSON (Introduced by William S. McCann), Rochester, N. Y.

Heretofore, interest in cardiac output has been concerned with methods and results rather than relationships of the factors concerned. The determinants of cardiac output can be expressed by various equations relating heart rate, stroke volume, oxygen consumption, ventilation and arteriovenous oxygen difference. This study is a statistical analysis of the available data both in the literature and from our "Chest" Laboratory.

The results indicate that there is a linear increase in cardiac index from the basal state to that of severe exercise and that the rate of change seems to be fairly constant despite the method used to determine it. For each 10 per cent increase in oxygen consumption there is a 7 per cent increase in cardiac index. The arteriovenous oxygen difference shows a gradual widening with exercise but this change is minimal constituting only about 10 per cent of the total increase. Heart rate increases more than stroke volume with an increasing cardiac output. Total ventilation is directly related to either heart rate or cardiac index during exercise. As oxygen consumption increases with exercise, approximately 90 per cent of the change is accounted for by increasing ventilation whereas only 10 per cent is made up by the increase in the volumes per cent oxygen absorbed from air. The oxygen transported per heart beat reflects more of a change in arteriovenous oxygen difference than in stroke volume. Slides are presented to illustrate these changes.

Clinical Study of 11-Dehydro-17-Hydroxy-Corticosterone in Hypertension, Addison's Disease and Diabetes. GEORGE A. PERERA and (by invitation) KENNETH L.

PINES, HOWARD B. HAMILTON and KATHERINE VISLOCKY, New York, N. Y.

The present study was undertaken in order to determine the clinical and metabolic effects of synthetic 11-dehydro-17-hydroxy-corticosterone acetate (Cpd. E.) (Merck). Because of the possibility that this steroid might exert a depressor action on the arterial tension, in addition to its reported modification of carbohydrate metabolism, observations were made on four patients, two with uncomplicated hypertensive vascular disease, one with Addison's disease, and one with diabetes mellitus and hypertension.

Observations were made after an adequate baseline and on a constant regimen. Cpd. E was administered intramuscularly (20 mgs. every 6 hours) for periods usually of eight days.

At least transitory salt and water retention was observed, but an increased nitrogen excretion was not consistently apparent. Serum electrolyte values were not materially affected. A slight decrease in cholesterol esters was noted. Urinary 17-ketosteroid and "corticoid" excretion did not change significantly. Blood sugars, after 17 hours' fasting, and glucose tolerance tests were minimally altered, but the results were of doubtful significance. Transitory ketonuria appeared in some subjects. Cpd. E produced an increase in total white cell count, together with a pronounced drop in eosinophiles. Percentage uptake of radioactive iodine in the patient with Addison's disease fell slightly.

Cpd. E exerted a depressor effect on the "resting" blood pressure of the hypertensive patients.

The Use of Intravenous Human Albumin in Decompensated Cirrhosis of the Liver. JOSEPH POST and (by invitation) JEROME V. ROSE, Bronx, N. Y.

Human albumin was administered intravenously to sixteen patients critically ill with decompensated cirrhosis of the liver, for about three months, in amounts sufficient to maintain normal serum albumin levels. The dietary regime consisted of about 3,500 calories with 140 grams of protein, and supplementary B complex parenterally. Two patients had post-necrotic cirrhosis and fourteen were alcoholics with Laennec's cirrhosis. Due to the gravity of illness, the pre-treatment observation period was one to six weeks.

Of these sixteen patients, thirteen improved and had complete diureses, two showed only widening of the paracentesis intervals, and one had no effect (later died with hepatoma). Of the thirteen patients who had diureses, five died some weeks later of the following causes: "cholemia"—2; hematemesis—1; carcinoma of stomach—1; uremia—1. Seven patients who had diureses, were comatose when therapy was begun.

Six other patients, not included above, were in deep coma on admission and survived only two, two, three, seven, eight and thirteen days of therapy.

Thirty-two patients, with decompensated Laennec's cir-

rhosis of the liver, were observed during a period of six to eight weeks for control studies, while on the above dietary regime. These patients did not appear as seriously ill as were those treated with albumin. Twenty-one improved and diuresed without albumin treatment. Ten died of the following causes: "cholemia"—1; hematemesis—5; uremia—1; hepatoma—2; intestinal obstruction—1.

Intravenous albumin has a place in the therapy of decompensated cirrhosis of the liver.

The Nature of Auricular Flutter. MYRON PRINZMETAL, and (by invitation) I. C. BRILL, ELIOT CORDAY, ALVIN L. SELLERS, WALTER A. FLIEG and H. E. KRUGER, Los Angeles, Calif.

The present concept of auricular flutter, based upon the classical studies of Lewis and his coworkers, is that this arrhythmia is due to a pure circus movement moving down one auricle and up the other, ringing the venae cavae. Lewis believed that daughter waves were emitted to the periphery of the auricles from the main circus path. By taking slow motion pictures (2000 frames per second) of fluttering auricles, (250 times slower than normal speed) the flutter wave can be readily seen. When flutter is produced by placing aconitine in the center of the surface of the right auricle it can be seen that the flutter contraction travels in *all* directions from the ectopic focus and not in *one* direction as would be demanded if Lewis's circus movement were the cause of flutter. No daughter waves of contraction are visible. A burn placed across the path of the theoretical circus wave does not interfere with the flutter. Flutter contractions appear similar to the contractions in paroxysmal tachycardia. The main difference is that flutter is due to more rapid discharge from the ectopic auricular focus with varying degrees of A-V block. Auricular flutter results when an ectopic focus discharges itself at a faster rate than in paroxysmal tachycardia but slower than in auricular fibrillation. The flutter wave does not pursue a circular course but travels in all directions from the site of impulse formation by all available routes.

Differential Diagnosis of Adult Rheumatic Fever and Rheumatoid Arthritis by Means of Serological Tests.

R. W. QUINN and S. J. LIAO (Introduced by John R. Paul), New Haven, Conn.

Serological studies are reported on series of cases as follows: (i) 50 cases of active rheumatic fever; (ii) 42 cases of inactive rheumatic fever (both groups (i) and (ii) largely adults); (iii) 40 cases of acute beta hemolytic streptococcal upper respiratory infections; (iv) 35 adult cases of rheumatoid arthritis, and (v) 45 normal subjects. One to six samples of blood from each of these subjects have been studied by means of a battery of tests, including, antihyaluronidase, antistreptokinase, antistreptolysin "O," and streptococcal agglutination with both autoclaved and live organisms.

The introduction of two relatively new tests, namely (a) antihyaluronidase and (b) Thulin's agglutination technique employing autoclaved beta hemolytic streptococci, are significant points in this study. Their use places the former (a) in relation to the other streptococcal antienzyme tests and the latter (b) in relation to conventional agglutination tests using live organisms.

Results of these tests indicate that in active rheumatic fever all of the antibody titers except the agglutination titers are significantly higher than in the other groups studied. In inactive rheumatic fever titers are not significantly higher than in normal subjects, except in the case of the agglutination titers which were higher than normal. In patients convalescent from upper respiratory hemolytic streptococcal infections, the titers of all four tests are higher than in those with inactive rheumatic fever, rheumatoid arthritis or normal subjects.

Similarities in the clinical pictures of adult rheumatic fever and rheumatoid arthritis are discussed along with the serological means now at our disposal for differentiating these two conditions. This discussion indicates that in any individual case, high titers in any one or all of the anti-enzyme tests and a high agglutination titer would seem to favor a diagnosis of rheumatic fever, whereas low anti-enzyme titers and a high agglutination titer would favor a diagnosis of rheumatoid arthritis.

Study of a Human Cystinuric Fed Radioactive Methionine. LESTER J. REED, DORIANO CAVALLINI, FRED PLUM, JULIAN R. RACHELE and VINCENT DU VIGNEAUD (Introduced by Robert F. Watson), New York, N. Y.

Studies on human and experimental animals having spontaneous cystinuria have clarified some of the steps in organic sulfur metabolism. A source of urinary cystine sulfur has been proved to be ingested methionine in dogs through the use of radioactive sulfur (S^{35}). The present communication extends this type of approach to the human.

Through the incidental finding of a spontaneous cystinuria of from approximately 0.3 to 0.5 gm. per day in a patient with a post-meningitis convulsive disorder, we were provided the opportunity to study this cycle. Radioactive sulfur (S^{35}) in methionine (200 mg.) was given this patient in an amount considered safe by the standards of the Health Physics Department at Oak Ridge, Tennessee.

Following the ingestion of tagged methionine, radioactive sulfur (S^{35}) was found in the cystine of this patient's urine within 24 hours, and later was detected in the cystine of her hair. This unequivocally demonstrated that cystine sulfur may arise from ingested methionine. Coincidentally with the feeding of the S^{35} the patient had a transient increase in capillary fragility, fall in hemoglobin and decrease in red blood count. There had been an associated nutritional difficulty with the convulsive disorder. These abnormalities responded to iron therapy and the treatment of the primary clinical difficulty, and an 18 month follow-up has revealed no abnormality attributable to the radioactive sulfur.

The Action of Insulin on Glycogen Deposition in Adipose Tissue. ALBERT RENOLD and D. W. FAWCETT (by invitation) and ALEXANDER MARBLE, Boston, Mass.

The observations here reported were made during a study of lipodystrophies due to insulin. A promising line of approach was suggested by the report of Fawcett in 1948 who called attention to histological studies demonstrating under certain conditions considerable amounts of glycogen in fatty tissue.

In our studies the glycogen in the fat of diabetic rats was determined chemically and found to be negligible in untreated animals whereas amounts as large as 1.5-3.0 per cent of the fresh weight of fat could be demonstrated 24 hours after a single large dose of insulin. This action of insulin could be shown to be both local and systemic.

Young, female, alloxan-diabetic rats (40 animals) were subjected for 65 days to daily injections of 3-5 units of protamine zinc insulin into the fat pad of one groin, with control injections of saline into the other groin. The insulin-injected fat pad showed an increase in weight averaging 55 per cent, an increase in total ether-extractable material averaging 66 per cent and a definite increase in the size of individual fat cells. The ability to deposit glycogen under the influence of insulin was not consistently altered at the site of the prolonged injections.

From these data it is concluded that there is evidence of a local metabolic action of insulin in adipose tissue. This action might be attributed to the increased production of metabolically available carbohydrate—glycogen—therefore to a possible favoring action on the conversion of carbohydrate to fat in the adipose tissue itself. Considerable evidence for the existence of extrahepatic lipogenesis is available in the literature.

The Relation of Effective Pulmonary Blood Flow to Total Pulmonary Blood Flow in Normal Man and in Patients with Various Types of Chronic Pulmonary Disease. RICHARD L. RILEY, ROBERT AUSTRIAN, KENNETH W. DONALD and ANDRE COUNNAND (Introduced by Dickinson W. Richards, Jr.), New York, N. Y.

With knowledge of the composition of inspired and expired air, the respiratory quotient and the tensions of O_2 and CO_2 in systemic arterial blood, it is possible to determine indirectly the composition of alveolar air and of pulmonary capillary blood that would obtain if homogeneous equilibrium existed between blood and gas phases throughout the lung. When the composition of mixed venous blood is also determined, one can compute the proportions of mixed venous blood and of effectively oxygenated pulmonary capillary blood that, when mixed, would yield blood of the composition found in the systemic arteries. Effective pulmonary blood flow is defined as the product of total cardiac output times the calculated proportion of effectively oxygenated pulmonary capillary blood.

In normal individuals, effective pulmonary blood flow averaged 95.8 per cent of total pulmonary flow. In patients with pulmonary suppuration and in those with pul-

monary fibrosis, the effective fraction of total flow averaged 92 per cent and 88 per cent respectively. In a group of patients with severe emphysema, the average effective fraction of flow was 69 per cent, a value only slightly higher than that found in a proven case of pulmonary arteriovenous fistula.

The Summation of Penicillin and Streptomycin Activity in Vitro and in the Treatment of Subacute Bacterial Endocarditis. WILLIAM C. ROBBINS (Introduced by David P. Barr), New York, N. Y.

Despite the therapeutic effectiveness of penicillin in subacute bacterial endocarditis, ultimate failure occurs in approximately 10 per cent of all cases because of inadequate suppression of the causative organism even by massive doses. Moreover, the use of streptomycin in these cases, most of which are caused by enterococci, has effected little improvement in the results.

An investigation has been made of the combined activity of penicillin and streptomycin *in vitro* with particular reference to the quantitative relationships of their combined action on strains of enterococci isolated from patients with endocarditis. It has been observed that penicillin and streptomycin act as adjuvants in inhibiting growth of enterococci. Total summation of partial effects has been found to occur throughout a wide range of concentrations of each constituent drug. For example, complete inhibition of growth is achieved with a mixture in which each drug is present in a concentration only half that of its own inhibitory concentration.

Five patients with persistent enterococcal bacteremia, four of whom had endocarditis, have received penicillin and streptomycin concurrently in doses of moderate size. Two patients received the combined therapy terminally, but three completed a four to eight weeks course of this therapy.

In all three patients bacteremia was promptly reversed and the immediate striking clinical improvement was sustained. The apparently complete recoveries have been maintained for six to fifteen months. Two additional patients are now under treatment.

The uniformly good results in these patients has been in striking contrast to the previous general experience with the use of either drug alone, and suggests the operation *in vivo* of a summative effect comparable to that observed *in vitro*.

The Effects of Oral Therapy with Cobaltous Chloride in the Blood. JOSEPH C. ROBINSON (by invitation), ROBERT M. KARK, (by invitation) MARY MALONEY, FREDERICK SARGENT, II, and GEORGE W. JAMES, Chicago, Ill., and Richmond, Va.

Although cobalt is an effective erythropoietic agent in cobalt deficient and healthy animals, its effects on the blood of healthy adults and of patients suffering with various types of hematologic disturbances have not been clearly defined. When administered orally cobaltous chloride (20 to 240 mgs. per day) induced anorexia in some patients but no other toxic symptoms were observed.

With the above dosage schedule, increased erythropoiesis was observed in 15 patients ill with chronic sepsis, in two patients suffering with skeletal neoplastic metastases, and in one patient with an unexplained long-standing refractory anemia. No erythropoietic response was noted in patients suffering with pernicious anemia when they were fed cobaltous chloride either alone or incubated with normal gastric juice. The drug was without effect in a patient ill with nutritional macrocytic anemia.

The blood of 15 young adults ill with chronic suppurative infection, when compared with the blood of 10 bedridden controls, showed abnormal iron and copper concentrations in plasma, a decreased red cell mass and a reduced total circulating hemoglobin. Following treatment with cobaltous chloride reticulocyte responses were observed in each patient. The maximal reticulocyte percentages were usually noted between the sixth and tenth day and did not exceed 5 percent in any patient. Thereafter, a steady increase was noted in red blood cell counts, in hematocrit values and in hemoglobin levels. The plasma volume changed but slightly whereas the circulating red cell mass and the total circulating hemoglobin increased about 30 percent.

In an attempt to explain the mechanism of cobalt activity on the basis of impaired cellular respiration, the blood of patients was examined spectrophotometrically. No abnormal concentrations of methemoglobin were observed.

Tyrosine Metabolism in Human Scurvy. WALTER F. ROGERS, JR., and FRANK GARDNER (Introduced by Robert F. Pitts), Syracuse, N. Y.

It has previously been reported that scorbutic guinea pigs, and premature infants fed high protein diets, have a defect in their metabolism of tyrosine which is corrected by vitamin C. These findings have prompted the study of tyrosine metabolism in 4 individuals with scurvy and in 4 normal persons.

After suitable control periods all individuals, with the exception of one scorbutic, received 20 grams of tyrosine by mouth daily for periods varying from five to thirty-one days. The patients with scurvy, while on a vitamin C free diet, and under this load of tyrosine, excreted large amounts of "tyrosyl" derivatives, and the power of their urine to reduce phosphomolybdic acid increased markedly, presumably due to the presence of p-hydroxyphenylpyruvic acid. Compared to normal individuals receiving 20 grams of tyrosine per day, the scorbutics excreted from seven to fifteen times the quantity of "tyrosyl" derivatives, and the power of the urine of scorbutics to reduce phosphomolybdic acid was twenty to thirty times that of normals, the urine of the latter showing no increased power to reduce phosphomolybdic acid during the administration of tyrosine. The administration of vitamin C to scorbutics during tyrosine loads completely corrected the metabolic abnormality in from twenty-four to forty-eight hours.

The administration of these large amounts of tyrosine

appeared to exacerbate the clinical condition of the individuals with scurvy.

Variations in the Electrophoretic Pattern of Synovial Fluid in Articular Disease. MARIAN W. ROPES and (by invitation) DOROTHY KAUFMAN and GERTRUDE E. PERLMANN, Boston, Mass.

As reported previously, comparison of the electrophoretic patterns of synovial fluid and serum in rheumatoid arthritis supports the hypothesis that there is increased permeability to protein of the tissues interposed between the blood and the joint space. In some of the fluids the distribution of proteins followed closely that found in the corresponding serum. In other cases there was a marked elevation of gamma-globulin in the synovial fluid despite a relatively low concentration of this component in the serum.

Study of electrophoretic patterns of synovial fluids from traumatic arthritis suggests that there is differential permeability to individual protein fractions. Albumin was always higher in the fluid than in the serum, alpha-1 and beta-globulins essentially the same, and alpha-2 and gamma-globulins lower in the fluid.

Further study of rheumatoid fluids has indicated some correlation between the electrophoretic pattern of the synovial fluid, the clinical features of the involved joints and the other characteristics of the fluid. In patients with early or mild involvement of the joint studied, the electrophoretic pattern usually resembled that of traumatic fluids, with albumin higher in the fluid than in the serum and gamma-globulin in equal or lower concentration in the fluid. In cases with longer duration or greater severity of inflammation in the joint studied, the electrophoretic pattern tended to be different. The albumin concentration was equal in the fluid and serum and the gamma-globulin higher in the fluid.

The electrophoretic pattern described in the previous report, with marked elevation of the gamma-globulin in the fluid above that in the serum, was found in three cases showing atypical clinical pictures. In these patients, large effusions had been present for one to eight years, but there was relatively little objective evidence of joint damage and other studies of the synovial fluid indicated relatively mild inflammation.

The Inhibitory Effect of Secretions of the Human Respiratory Tract on Influenza Virus. HARRY M. ROSE, New York, N. Y.

Aqueous preparations of sputum from individuals with a number of diseases accompanied by cough and expectoration contain variable amounts of a substance which will inhibit the agglutination of erythrocytes by influenza virus type A (PR8) and B (Lee). This inhibitor is not specific antibody and is unrelated to the mucin content of sputum, as determined by the ACRA test, or to the level of antibodies in the blood. It acts directly on the virus and not by altering the erythrocyte.

The inhibitor is moderately heat stable but is destroyed in 30 minutes at 100° C. Its activity is essentially un-

changed over a pH range from 4.0 to 8.0. It may be partially purified and concentrated by treating sputum with chloroform, followed by precipitation with ethanol at low temperature. The partially purified material is more stable on storage than the original sputum.

The titer of inhibitor is higher against influenza virus heated to 56° C. for 30 minutes than it is against the same number of agglutinating units of living virus. This effect is more pronounced with Lee than with PR8 virus.

The inhibitor is destroyed by exposure to living PR8 virus but not by exposure to heated virus. Its activity is also moderately reduced by treatment with the R.D.E. of *Vibrio cholerae*.

Mixtures of inhibitor and PR8 virus which fail to agglutinate erythrocytes when first prepared show a progressive rise in hemagglutinin titer on standing at 37° C. This is interpreted to indicate the release of virus from an inhibitor-virus complex. Such eluted virus may or may not show a reduction in its infectivity for chick embryos.

Preparations of the inhibitor may neutralize up to 1,000 minimal infectious doses of PR8 virus in mice. Previous treatment of the inhibitor with living virus reduces its neutralizing potency.

Effect of Urethane (Ethyl Carbamate) in Multiple Myeloma. R. WAYNE RUNDLES, M. L. DILLON, EDITH S. DILLON and JOHN ARMSTRONG (Introduced by David T. Smith), Durham, N. C.

Eleven patients with multiple myeloma have been treated with urethane. One could not tolerate the chemical and three died in 1-5 weeks. Seven patients were given 120-240 grams of urethane in 8-10 weeks and the course of their disease studied over periods up to 16 months. Striking clinical benefits were observed, including subsidence of fever, relief of skeletal pain, and gain in weight and strength. Incapacitated individuals were able to resume normal activities.

Measurable improvement related to all aspects of the disease. Abnormal plasma or "myeloma" cells became fewer or disappeared from the bone marrow and showed morphologic changes indicative of retarded or arrested growth. Four individuals had severe anemia. After urethane therapy abnormal cells disappeared from the circulating blood. The hemoglobin and red cell values improved, in three cases to normal levels. There was no progression in the osteolytic skeletal lesions as judged by serial roentgenograms. Bony recalcification was demonstrable in individuals with extensive skeletal disease after 4-6 months. Serum calcium levels when elevated fell to normal. The serum proteins were studied by electrophoretic methods in five patients. After two months of urethane therapy the abnormal globulin components decreased conspicuously or virtually disappeared. The amount of Bence Jones protein in the urine decreased. There was no association between the type of serum protein abnormality or the amount of proteinuria and renal function impairment. Nitrogen retention did not develop after urethane therapy.

Incomplete remissions of the disease have been observed as well as relapses 2-6 months after discontinuing urethane. Successive courses of urethane were given with good results. Despite these reservations the therapeutic benefit of urethane in multiple myeloma exceeds that of any other agent in use at this time.

Fatal B Virus Encephalomyelitis in a Physician Working with Monkeys. ALBERT B. SABIN, Cincinnati, Ohio.

This is to report for the second time in the past 16 years that a physician, aged 25, engaged in experimental work with rhesus monkeys, died from an infection of the central nervous system due to B virus, which occurs in monkeys much like herpes simplex virus occurs in man. The first case, a fatal acute ascending myelitis, from which the B virus was isolated and identified, occurred in 1932 in a young physician who was bitten by a monkey. In the present case there was no bite, but the infection apparently resulted from contamination by monkey saliva of a minor cut on the right index finger. This was followed by an insignificant lesion at the site of the cut, lymphangitis, lymphadenitis, and within a few days thereafter by a febrile illness during which the following significant neurological manifestations were observed in the order mentioned: crops of small herpetic-like lesions on the inner aspect of the right forearm, arm, axilla and anterior chest wall associated with soreness and burning sensation, dysphagia, increasing mental confusion, absent deep tendon reflexes in lower extremities, inability to expel enema, urinary retention, bilateral nystagmus, irregular respiration and finally cessation of respiration. The most severe lesions were found in the gray matter of the posterior and lateral horns of the spinal cord, in adjacent areas of the white matter, in the regional spinal ganglia, and medulla. An infectious agent possessing the properties previously described for B virus was recovered from the affected right axillary lymph node and central nervous system, by inoculation of rabbits. Mice proved to be relatively refractory and passage was not possible in them. No virus was found in the patient's cerebrospinal fluid, liver and spleen. The virus recovered from the patient was neutralized by a specific B virus antiserum.

Unusual Serological Findings in a Group of Cases of Pneumococcal Pneumonia Associated with the Presence of Influenza Virus in the Sputum. JONAS E. SALK and (by invitation) MARY P. LYNCH, Pittsburgh, Pa.

Between October 1948 and February 1949, when influenza was not occurring epidemically in the area in which these observations were made, 73 cases of pneumonia were studied, 5 of which yielded influenza virus upon inoculation of sputum into developing chick embryos. The viruses isolated in these cases, and from an additional case of influenza-like illness, were all found to be related antigenically to the A-prime group of influenza virus Type A. *Pneumococcus* Type I was found in the sputum of 2 cases, Type II in two other cases, and Type XVI in the sputum of the fifth case. Bacteremia was present in three instances; the patients with Type I pneumonia were found

to have 1,260 and 306 colonies per cc. of blood, respectively, and one with Type I pneumonia had 11 colonies per cc.

It is of particular interest that the presence of the virus in the sputum of these patients would not have been surmised from the results of the serological studies employing the hemagglutination-inhibition test and the complement-fixation test. Even with homologous antigens, these tests failed to reveal any increase in antibody in convalescence. However, definite evidence of antibody increase was observed in one case, and suggestive evidence in another, by a method involving virus neutralization tested *in ovo*.

Although a satisfactory explanation for the vagaries in the serological findings is not immediately apparent, several plausible possibilities exist. These are at present under investigation and will be presented and discussed.

The Effects of Postural Changes, Stellate Ganglion Block, and Anemia on the Cerebral Circulation. PERITZ SCHEINBERG (Introduced by W. M. Nicholson), Durham, N. C.

Many mechanisms influencing cerebral circulation can now be reinvestigated semi-quantitatively by the nitrous oxide technique for cerebral blood flow, devised by Kety and Schmidt. This technique was modified by drawing continuous 10-minute samples of arterial and internal jugular blood, thus allowing the body to integrate the mean nitrous oxide contents rather than calculating them mathematically from 5 separate arterial and venous samples.

Effective cerebral arterial pressure was reduced by tilting to an angle of 65° from the horizontal. Unilateral release of sympathetic tone was accomplished by procaine block of the stellate ganglion. Patients with anemia had: (1) chronic blood loss of varying durations; (2) pernicious anemia.

In 13 normals the average reduction in effective mean arterial pressure on tilting was 34 per cent. Average decrease in cerebral blood flow was 21 per cent, with average increase in cerebral arterio-venous O₂ difference of 23 per cent. Cerebral O₂ utilization (cerebral blood flow × A-V O₂) did not change. Average cerebro-vascular resistance (mean arterial pressure ÷ cerebral blood flow) fell 16 per cent. Average fall in internal jugular venous pressure was 60 mm. H₂O.

Stellate blocks were done on 16 subjects. These fell into 3 groups: (1) normal young individuals; (2) elderly patients with diffuse vascular disease; and (3) elderly patients with acute cerebral vascular accidents. There was no significant change in cerebral blood flow, O₂ utilization, or cerebro-vascular resistance following stellate blocks in any of the groups.

In 7 patients with anemia from chronic blood loss cerebral blood flows were increased greatly over the normal; the cerebral A-V O₂ differences were proportionately reduced, giving normal values for cerebral O₂ utilization. The cerebro-vascular resistance was markedly diminished in all.

In 5 patients with pernicious anemia the cerebral oxygen utilization was strikingly decreased. In one the value was normal.

Renal Insufficiency Caused by Overhydration or Depression of Sodium Chloride: The "Low-Salt Syndrome."
HENRY A. SCHROEDER, St. Louis, Mo.

Under certain circumstances, especially when there is slight impairment of renal function due to the aging process, hypertension or congestive circulatory failure, oliguria leading to renal excretory insufficiency may develop rapidly. When the intake of sodium chloride is restricted and the intake of water is not, or when depression of body salt and not of water is induced, the result is nitrogen retention, dilution of extracellular electrolytes, overhydration and probably hydration of cells. Death occurs from uremia. This condition was encountered in over 30 cases, of which 10 died, under the following circumstances: (a) In congestive failure after the enthusiastic use of mercurial diuretics, (b) In congestive failure with slight renal damage when the intake of fluids was rapidly elevated, (c) In arterial hypertension with moderate renal insufficiency when the intake of salt was severely restricted, (d) Post-operatively, in older individuals, when the concentration of plasma electrolytes was diminished by too vigorous use of glucose in water, (e) When excessive electrolyte losses from surgical drainage (bile, etc.) had occurred. While the electrolyte pattern resembled that seen in anuria from other causes when fluids and not salt were given, renal function could be often restored by increasing the concentration of the electrolytes in extracellular fluids to normal levels. The intravenous injection of hypertonic saline solution (5-6 per cent), in an amount sufficient to replace the calculated deficit in extracellular fluids, was the method of choice. When this was used, diuresis often became established and renal function returned toward normal. No adverse effects from the use of hypertonic salt were observed or expected when electrolyte levels were depressed even in the presence of general anasarca, pulmonary congestion, and elevation of the venous pressure. The early recognition of oliguria due to overhydration or salt depletion is necessary for therapy to be effective. It is probable that many cases of so-called "post-operative," "reflex" and "essential" anuria are the result of overhydration. Shock was not necessary for the situation to develop.

Some Biochemical Effects of Radiation. SAMUEL SEHWARTZ (Introduced by Jay C. Davis), Minneapolis, Minn.

The effect of relatively large amounts of ionizing radiation on several biochemical systems has been studied in human subjects and in experimental animals (dogs, rabbits, and rats). The following changes have been observed:

- (1) There is a marked rise in excretion of urinary corticosteroids in human subjects.
- (2) There is a significant increase in bile pigment excretion indicating that radiation anemia is in part hemolytic in nature.

- (3) There is a marked fall in the urinary and fecal excretion of coproporphyrin.
- (4) Evidence of liver dysfunction is found shortly after the irradiation and especially during the several days preceding death.
- (5) Marked increases are often found in the urinary urochrome reaction in humans. Another tryptophane derivative, kynurenic acid, is excreted in increased amounts by dogs.
- (6) Increases are often observed in the adenosine triphosphate fraction of the circulating white blood cells. (This may be noted with relatively small amounts of radiation, but is not uniform.)

Excretion of Sodium Following Sulfanilamide Administration in Congestive Heart Failure. WILLIAM B. SCHWARTZ (Introduced by Samuel A. Levine), Boston, Mass.

It has been the hypothesis in this study that inhibition of carbonic anhydrase in the renal tubules should result in an increased excretion of sodium. Since the acidification of the urine appears to be effected by hydrogen ions within the renal tubular cells being exchanged for sodium ions in the glomerular filtrate, it was postulated that diminished tubular excretion of hydrogen should lead to a decreased reabsorption of sodium. For this reason sulfanilamide, a specific inhibitor of carbonic anhydrase, has been administered in an effort to lower the rate of formation of carbonic acid in the renal tubules and thus reduce the source of hydrogen ions available for excretion. Seven subjects in refractory congestive heart failure on constant fluid and food intakes have received sulfanilamide in doses of three to six grams per day for periods of two to eight days. Increased excretions of sodium averaging three to four times the control values have resulted in each case. There was also, in most instances, a prompt increase in potassium and water excretion and loss of weight proportional to the increased sodium excretion. At the same time there was a fall in the carbon dioxide combining power of the serum and an elevation of the serum chloride level. Significant improvement in the signs and symptoms of congestive heart failure occurred in five out of seven patients. Other compounds with unsubstituted sulfonamide groups which are inhibitors of carbonic anhydrase are under investigation in an effort to find a substance less toxic than sulfanilamide.

The Effect of Endocrine Therapy on Hormonal Excretion in Patients with Carcinoma of the Breast with Extension. ALBERT SEGALOFF and (by invitation) RICHARD L. COPPEDGE, New Orleans, La.

Studies of various hormonal excretions have been done in patients with metastatic carcinoma of the breast. Many of the patients showed levels of gonadotrophic hormone excretion much lower than one would expect from their age and endocrine status. This is believed due to their advanced cachectic state as were the low ketosteroid values observed in many of these same patients. In the patients in whom gonadotrophic hormones were sufficiently high before the initiation of therapy, both estrogens and androgens

gens produced the expected decrease of gonadotrophic hormone in the urine. Most of the patients receiving testosterone propionate showed the expected rise in ketosteroid excretion and androgen excretion. However, two of the patients with previously low ketosteroid values had no increase in ketosteroid excretion.

In 3 of the 6 patients in whom follow-up cortins were obtained, there was a very distinct rise in the excretion of cortin while on testosterone therapy. In the one patient under estrogen therapy in whom this has been studied, there was no change in the excretion of cortin in the urine despite a favorable clinical response to the estrogen.

In 3 of the 4 patients in whom the urinary excretion of lactogenic hormone has been studied before and during therapy with testosterone, there was a distinct rise in prolactin excretion during the therapy with testosterone. In one of these 3 patients, estrogen produced no further change.

There has been no very striking correlation between the clinical course observed in any of these patients and the hormonal changes in the urine. However, the patients obtaining the best clinical responses to testosterone were the patients who showed the increases in cortin excretion.

The Metabolism and Excretion of Electrolytes and Glucose in Diabetic Acidosis. DONALD W. SELDIN and ROBERT TARRIL (Introduced by David M. Kydd), New Haven, Conn.

Fifteen patients, studied during the early stages of diabetic acidosis, received repeated moderate or massive injections of glucose. Utilization and storage of carbohydrate probably occurred within the first two to three hours of treatment, since the injected glucose could not be completely recovered in the extracellular fluid or urine. The large increment of administered glucose which was excreted after massive injections resulted in a striking increase in urine flow despite dehydration. Potassium was not swept into the urine by the osmotic action of glucose within the renal tubule, since the excretion of the ion was highest initially and fell progressively notwithstanding marked increases in glycosuria. The excretion of sodium and chloride, in contrast, appeared to be augmented by infusions of glucose, although this response was modified by adaptive reactions such as conservation of sodium in the maintenance of acid-base equilibrium.

The serum concentrations and urinary losses of potassium and phosphorus were highest initially, and fell progressively during treatment. The high serum concentrations resulted from the failure of the initially accelerated excretion to keep pace with the effects of rapid cellular release of the ions and a contracting extracellular volume. After treatment was instituted, however, the discharge of potassium and phosphorus from cells was progressively retarded. Indeed, positive intracellular balances of phosphorus were observed in six of seven patients and of potassium in two of eight patients. The slow cellular release of the ions (possibly due to increased utilization of carbohydrate and diminished catabolism of protein), in conjunction with continuing losses in the urine and expansion

of extracellular volume were responsible for the fall in the serum concentrations.

The Effect of Lumbodorsal Sympathectomy upon Insulin Tolerance in Man. F. A. SIMEONE (Introduced by Oliver Cope), Boston, Mass.

The insulin tolerance of non-diabetic hypertensive patients selected for lumbodorsal sympathectomy did not differ from that of non-diabetic non-hypertensive patients of the same age group. In the cat, dog, and rabbit, denervation of the adrenal glands renders the animals extraordinarily sensitive to insulin. In a previous report, it was demonstrated that, contrary to expectation, the insulin tolerance of patients who had had lumbodorsal sympathectomy was increased during the immediate postoperative period. This finding was interpreted as a manifestation of the adaptation syndrome.

Twenty-six patients have been studied approximately one year after lumbodorsal sympathectomy and the insulin tolerance curves have been compared with those before operation and with those immediately after operation in the same patients. The sensitivity to insulin a year after operation was significantly greater than it was before operation or soon after operation.

In three of the twenty-six patients, the increased sensitivity to insulin a year after operation was especially striking, the blood sugar concentration remaining 20 per cent below fasting as long as 180 minutes after the injection of insulin. One of these three had a convulsion after insulin, 0.08 units per kilogram of body weight intravenously. No other patient had a convulsion before or after operation.

In summary, lumbodorsal sympathectomy is attended by increased sensitivity to insulin demonstrable after a preliminary period of increased tolerance, a manifestation of the adaptation syndrome. In the majority of cases, however, the change in sensitivity is not great enough to be a useful test of adrenal denervation for the individual patient.

The Site of Action of Methyltestosterone in the Production of Creatinuria. ETHAN A. H. SIMS (Introduced by Arthur J. Geiger), New Haven, Conn.

It is generally accepted that methyltestosterone ingestion produces increased creatine synthesis, which is followed by creatinuria when the capacity to store creatine is exceeded. The initial rise in guanidoacetic acid (GAA) serum levels and excretion indicates accelerated GAA synthesis. It has not, however, been demonstrated that creatinuria may be produced solely by increased GAA synthesis. Failure to recover quantitatively exogenous creatine or GAA in balance studies, including a recent study in which the subject's tissue creatine was labeled with N-15, suggested that the methylation of GAA is retarded by excess creatine. If this were so, it would be necessary to postulate that methyltestosterone accelerates the methylation as well as the synthesis of GAA.

GAA tolerance tests made after the ingestion of 25 gm. of creatine gave results inconsistent with a retarded con-

version of GAA to creatine under these conditions. To determine whether GAA is in fact methylated when the tissues are loaded with creatine, a normal subject was given 2.5 gm. of GAA daily in 16 hourly portions after the body had been saturated by prolonged creatine ingestion. A creatinuria averaging 0.48 gm. was seen during the following 21 days. The creatinine excretion did not fall during this period, suggesting that the urinary creatine did not originate from body creatine. All creatine values were corrected for glycohydrazide. GAA excretion averaged 0.55 gm. per day during the period of creatinuria. No evidence suggesting retardation of methylation of GAA was found under these conditions. It was thus possible to simulate the creatinuria from methyltestosterone by administering GAA in physiological amounts. This suggests that the direct action of the steroid on creatine metabolism may be solely that of accelerating GAA synthesis.

The Dynamics of the Cellular Response of Lymph Nodes to Acute Bacterial Infection. RALPH O. SMITH (by invitation) and W. BARRY WOOD, JR., St. Louis, Mo.

In order to define more precisely the role of lymphatic tissue in the cellular mechanism of antibacterial defense, a study was made of the pathogenesis of acute popliteal lymphadenitis produced in rats by inoculation of the footpad with Type I pneumococcus. Early in the course of the infection the bacteria reaching the popliteal node via lymphatics caused a rapid exudation of polymorphonuclear leucocytes within the nodal sinuses. The granulocytes which accumulated in the intermediary sinuses were found to come primarily from capillary blood vessels of the node, whereas the majority of inflammatory cells in the subcapsular sinus arose from the primary focus of infection in the foot. The granulocytes in the sinuses, carried toward the hilus by the continuous flow of lymph, formed a "log jam" of cells through which invading bacteria were forced to pass. The hilar accumulation of cells greatly increased the filtration efficiency of the node, and pneumococci caught among the phagocytes were promptly ingested. Mast cells lining the sinuses were noted to discharge their heparin containing granules into the nodal lymph. Whether this mast cell reaction accounts for the failure of lymph within the node to clot or whether the released heparin plays some other role in antibacterial defense is now being investigated. It is concluded that lymph nodes, often regarded as passive filters in the lymph stream, in reality react promptly to bacterial invasion and provide an active cellular barrier to bacterial invasion of the blood stream.

Liver Function Studies in Amebiasis. W. A. SOREMAN and (by invitation) A. A. DOERNER, New Orleans, La.

Liver function tests (cephalin flocculation, thymol turbidity, quantitative blood bilirubin, bromsulphalein) were done in a group of 51 patients with colonic amebiasis in the absence of dysentery, clinical evidences of malnutrition and past history of hepatic disease. They fell into four groups: (1) Acute amebic abscess, (2) Acute amebic

hepatitis without demonstrable abscess, (3) Colonic amebiasis with tender hepatomegaly but without systemic response, and (4) Colonic amebiasis without demonstrable hepatomegaly. Tests were done before therapy was instituted and, where possible with abnormalities, after therapy was completed.

Approximately 50 per cent of those in groups 1 and 2 showed evidence of hepatic damage, chiefly with the cephalin flocculation test and with minor elevations of the blood bilirubin. In 10 per cent there was clinical jaundice. In group 3 the tests were positive in about 20 per cent and, like group 4, were spotty and irregular.

These studies indicate that (1) in the absence of a febrile response, the variability of results was not striking. (2) Although diffuse damage occurs in the liver from amebiasis and is reflected in liver function tests, the process at times may reach advanced stages with no more evidence of involvement, by the techniques used, than in those with subclinical involvement. (3) The number of such discrepancies between the clinical findings and the liver function tests used is in contrast with that seen in some other acute conditions of the liver and may be helpful at times in differential diagnosis. (4) Moderate degrees of hepatomegaly, unexplained and without confirmatory positive tests of liver function, are at times the chief physical findings of amebiasis and should lead to search of the colon for this disease. (5) Amebiasis may, at times, without clinical signs of hepatic involvement give evidence of hepatic involvement with the liver function tests used.

Coronary Blood Flow and Cardiac Oxygen Consumption in Unanesthetized Dogs. F. C. SPENCER, S. R. POWERS, D. L. MERRILL and R. J. BING (Introduced by Cowles Andrus), Baltimore, Md.

In a large series of experiments on trained, unanesthetized dogs, the coronary blood flow through the left ventricle has been determined by the combination of coronary sinus catheterization and the nitrous oxide method. A catheter was inserted into the coronary sinus through the external jugular or cephalic vein; arterial blood was collected from the femoral artery. Following a ten-minute saturation with 15 per cent nitrogen oxide, samples were collected over a desaturation period of eight minutes. Mixed venous blood was collected simultaneously through a separate catheter in the pulmonary artery. Left ventricular weight was calculated from the tables of Herrmann.

The left ventricular flow averaged 151 cc./100 grams/minute, the coronary arterio-venous oxygen difference 12.8 vol. per cent, and the oxygen consumption of left ventricular muscle 19.5 cc./100 gram/minute. The oxygen consumption of the whole left ventricle averaged 11.3 cc. of oxygen/minute. The left ventricular efficiency

$$\left[\frac{\text{left ventricular work (kgm. meters)}}{\text{energy cost of whole left ventricle (kgm. meters)}} \right]$$

calculated from an average cardiac output of 4,450 cc./minutes and a mean aortic pressure of 119 mm. Hg was found to be 30.7 per cent.

It may be concluded that in the unanesthetized dog the left ventricular flow and oxygen consumption per unit

weight are twice as high as in the anesthetized dog (Edcnhoff *et al*). Accordingly the left ventricle efficiency is within the range observed in normal man.

Metabolic Effects of Synthetic Compound E (17-Hydroxy-11-Dehydrocorticosterone) in 2 Patients with Addison's Disease and in 1 with Coexisting Addison's Disease and Diabetes Mellitus. RANDALL G. SPRAGUE and (by invitation) MARSCHELLE H. POWER, HAROLD L. MASON and HARLEY E. CLUNTON, Rochester, Minn.

Response to the administration of synthetic compound E (17-hydroxy-11-dehydrocorticosterone) was studied in 2 female patients with Addison's disease and in 1 with both Addison's disease and diabetes mellitus during treatment with 11-desoxycorticosterone. Compound E acetate was administered intramuscularly as an aqueous suspension of finely ground crystals in doses of 50 and 100 mg. daily, respectively, to the 2 patients with Addison's disease, and in doses of 30 mg. to the patient with both Addison's disease and diabetes. In another study, the last patient received 25 mg. of free compound E daily.

Under the conditions of these studies, compound E produced no significant change in the urinary excretion of sodium, potassium or chloride. Likewise, minor changes in the excretion of nitrogen, calcium and phosphorus were probably not significant.

During treatment with compound E, both patients with Addison's disease were able to fast without decline of the level of the blood sugar. A minor reduction in sensitivity to insulin, and higher levels of the blood sugar in the course of glucose tolerance tests were also observed. In the case of coexisting Addison's disease and diabetes mellitus, carbohydrate effects of the hormone were more easily demonstrated. During treatment with compound E, there was a marked increase in urinary glucose, in spite of the daily administration of 4 or more times the amount of insulin employed in the control periods.

During and following periods of administration of compound E acetate, the urinary 17-ketosteroids and corticosteroids increased above the control levels. In 1 patient, the excretion of these substances remained elevated for a period of four weeks after the administration of compound E acetate was discontinued, and there was evidence of persistence of its physiologic effects during this time, suggesting that the steroid was absorbed slowly from the sites of injection.

The results demonstrate the predominant carbohydrate activity of compound E. The hormone was excreted in part as a 17-ketosteroid.

Cardiovascular-renal Dynamics and Electrolyte Excretion in Panhypopituitarism. J. STAMLER, A. P. FISHMAN and R. ROSENMAN (Introduced by L. N. Katz), Chicago, Ill.

Increased appreciation that hormonal factors influencing mineral exchange may play a role in the initiation and persistence of congestive heart failure led us to study the cardiovascular-renal dynamic changes in various endocrine disorders usually associated with electrolyte disturbances. This report presents the initial data in this investigation.

In two cases of panhypopituitarism, with B.M.R.'s of -48 and -23 respectively, studies of the cardiovascular-renal dynamic changes by cardiac catheterization and renal clearance techniques revealed the following changes: decreased cardiac output, cardiac index, circulation rate, renal blood flow, renal index (renal blood flow/cardiac output), glomerular filtration rate, and blood volume, and normal thiocyanate space and venous pressure.

Patient A presented symptoms suggestive of adrenal insufficiency (plasma Cl 90, Na 134 m. eq./L); patient B had no such findings (plasma Cl 102, Na 144 m. eq./L). With distal tubular function calculated on the basis (H. W. Smith) that there is an obligatory isotonic proximal tubular reabsorption of 85 per cent of the glomerular filtrate, renal clearance data reveal the following: In patient A, with plasma Cl concentration of 89-91 m. eq./L, 6.7-7.4 per cent of the Cl filtered (GFR: 47 cc./min.) is excreted; the overall tubular reabsorbate has a Cl concentration of 86-87 m. eq./L; distal tubular Cl reabsorption is at the rate of 0.3-0.4 m. eq./min.; the distal reabsorbate has a Cl concentration of 58-62 m. eq./L. In patient B, despite a higher plasma Cl concentration (94-104 m. eq./L) and despite a higher GFR (58 cc./min.) only 2.0-4.2 per cent of the Cl filtered is excreted; the overall tubular reabsorbate has a higher Cl concentration (102-114 m. eq./L); distal tubular Cl reabsorption occurs at a greater rate (0.7-0.8 m. eq./min.); by further contrast, the distal Cl reabsorbate is hypertonic (267-485 m. eq./L), and this cannot be accounted for by impaired H₂O reabsorption. Thus, the inadequacy of distal electrolyte absorption in patient A, even at low plasma Cl levels, contrasts markedly with that of patient B and accounts for the hyponatremia and hyponatremia in the former.

It is suggested that patient A, unlike patient B, is one of the more unusual cases of panhypopituitarism suffering from a secondary adrenal insufficiency involving the mineralocorticoids. In such a patient both the decreased demands upon the heart (low B.M.R.) and the decreased tubular reabsorption of electrolytes secondary to adrenal insufficiency mitigate against the development of congestive heart failure and edema, despite myocardial damage and low glomerular filtration rate (decreased presentation of Na to the renal tubules).

The Effect of the Iodide Ion on Thyroid Hormone Formation in Man. MALCOLM M. STANLEY (Introduced by E. B. Astwood), Boston, Mass.

The amount of iodine entering the thyroid normally provides an index of hormone formation. Stable thyroid iodine (I^{127}) accumulation can be estimated with radioactive I^{131} provided (1) That thyroid I^{131} can be measured and (2) That the specific activity of the collected I^{131} can be computed. $I^{127} = I^{131}/S.A.$

Nearly simultaneously, serially, urine I^{127} and I^{131} , serum I^{127} and thyroid I^{131} were determined, the last by counting at 35 centimeters from the gland. The kidneys excreted these isotopes in the urine in the same ratio in which they appeared in the serum: $SI^{127}/SI^{131} = UI^{127}/UI^{131}$. The renal and thyroid arterial blood iodide contents were identical; the urinary $I^{127}:I^{131}$ ratio reflected the specific activ-

ity of the thyroid radioiodide accumulated during the period. Serum iodide (I^{127}) = $SI^{127} \times UI^{127} / UI^{127}$.

The thyroids of these twenty controls with serum iodide levels around one microgram or less (without extra iodide) accumulated 5-16 micrograms I^{127} /hour, averaging 11 micrograms/hour. As serum iodide levels were raised to 6-12 micrograms per cent by iodide administration the iodine accumulated by the thyroid proportionally increased. With higher serum iodide levels inhibition of organic binding of iodide in the thyroid occurred, with subsequent complete blocking of uptake. This extended the observations of Wolff and Chaikoff in the rat. The thyroids in eight thyrotoxic patients accumulated an average of 122 micrograms I^{127} /hour; inhibitory serum iodide levels were less than five micrograms per cent.

With varying serum iodide values below inhibition the thyroid collects a constant fraction of the serum iodide. Probably the amount of iodide in the thyroid cells, rather than in the serum, determines the inhibitory point; with great ability to accumulate iodide (high thyroid: serum ratios) inhibition occurs with low serum iodide levels, and vice versa.

Fat in Intravenous Nutrition. FREDERICK J. STARE and (by invitation) SHERWOOD W. GORENS and ROBERT P. GEYER, Boston, Mass.

The inability to supply caloric requirements is a handicap in present-day parenteral therapy.

Work on the preparation of fat emulsions for intravenous use and on some of the metabolic aspects of the intravenous administration of fat has been under way in this laboratory. In the past year fat emulsions have been given to patients with varying degrees of success. A few cases will be mentioned of which the following is typical.

The patient was a 24-year-old white male with onset of frequent bloody mucous stools 7 years ago. A diagnosis of ulcerative colitis was made. Fifteen months prior to admission, he began to have 9 to 12 bowel movements per day and he lost 45 pounds. An ileostomy was performed. The ileostomy did not function properly, and the patient developed a peritoneal infection and a mid-jejunal fistula. It was necessary to reoperate to close the fistula. At this time the patient weighed only 90 pounds and was in an extremely poor state of nutrition. Oral intake was nil, and the usual parenteral therapy contributed no more than 400 calories per day. On the first postoperative day 300 ml. of a 15 per cent fat emulsion containing 1.6 calories/cc. were given; on the second day twice this amount was given. The patient showed marked clinical improvement and felt much stronger. For the next 10 days he received daily infusions of fat varying from 600 to 900 ml. and furnishing 960 to 1,440 calories. By this time oral intake of food was sufficient and all parenteral therapy could be terminated.

Summarizing, fat emulsions can be prepared which can be given intravenously without reaction, and which contribute appreciably to caloric intake without requiring large fluid volumes or prolonged infusion times.

The Serum Proteins in Portal Cirrhosis—Electrophoretic Studies. Effects of Therapy. KENNETH STERLING and WILLIAM E. RICKETS (by invitation), and JOSEPH B. KIRSNER and WALTER L. PALMER, Chicago, Ill.

Electrophoretic analyses of the serum proteins and liver function tests were performed on ten normal subjects and twenty patients with proven portal cirrhosis of the liver, with follow-up studies during the course of medical management in five patients.

The principal abnormalities observed in the serum proteins of 14 untreated patients were diminutions of the albumin fractions and elevations of the gamma-globulin fractions. Less frequently observed and usually less pronounced were elevations of the beta-globulin fractions. Of these 14 cases, seven with ascites and hyperbilirubinemia exhibited these alterations in marked degree, so that the gamma-globulin fractions usually approached or even exceeded the albumins. Seven patients without ascites manifested a considerable range of variation in the electrophoretic pattern from markedly abnormal to nearly normal in three cases without symptoms.

Serial electrophoretic studies and tests of hepatic function were done on five patients with ascites and hyperbilirubinemia during the course of medical management for nine months or less. Progressive change in the direction of normal coinciding with clinical improvement was observed during the administration of a high protein, high carbohydrate, high caloric diet. Infusions of plasma and concentrated human albumin were followed by pronounced and immediate elevations of the serum albumin values.

Six patients who had clinically recovered from severe portal cirrhosis and had been asymptomatic for more than two years were found to have electrophoretic patterns very close to normal.

These studies indicate that the alterations in the serum protein pattern in portal cirrhosis are not irreversible, but with prolonged medical management and clinical recovery, may revert practically to normal.

Alcohol and Homeostasis: The Uncompensated Water Diuresis Induced by Whiskey. MAURICE B. STRAUSS and (by invitation) JACK D. ROSENBAUM and WILLIAM P. NELSON, III, Framingham, Mass.

Although the diuretic effect of strong drink was commented upon by W. Shakespeare, modern scientific opinion has leaned toward the thesis that it is the large quantity of fluid so often simultaneously imbibed which provokes the increased urinary output. The occurrence of undue thirst following the ingestion of strong or even much diluted alcohol appears to be a matter of common knowledge albeit little concerning this may be found in scientific literature.

Five hours after breakfast, volunteers ingested 147 cc. of Bourbon whiskey or water. Following the former, the urine output was increased three-fold or more, but the excretion of strong electrolyte exhibited no significant deviation from the values observed after water.

In order to compensate for insensible water loss in the fasting, thirsting state, the urine should contain at least

a third more electrolyte than the body fluids if hypertonicity of the latter is to be avoided. Since, after whiskey, the urine was observed to contain as little as one-fourth the electrolyte of body water and to be excreted in rather large volume, it is apparent that whiskey defeats the wisdom of the body and significantly disturbs homeostasis.

The rather constant glomerular filtration rate observed indicates that whiskey diuresis results from decreased tubular absorption of water. Evidence suggests that this is not due to a direct effect of whiskey on the tubules but rather an effect mediated through the supra-optico-hypophyseal mechanism.

No evidence was obtained of any alteration in the distribution of water between cells and extra-cellular fluid except that which would be anticipated as a result of the induced osmotic changes.

Both in the control and the whiskey studies the excretion of strong electrolyte often exhibited three-fold variation in spite of the fact that the amount of filtered electrolyte remained constant or varied in the opposite direction. Glomerular filtration of strong electrolyte would appear to be of less significance in controlling the rate of electrolyte excretion than has recently been suggested.

Studies of Formation, Diffusion and Absorption of Constituents of Cerebrospinal Fluid in Man. I. Studies with Na²⁴. W. H. SWEET, B. SELVERSTONE, A. SOLOMON and L. BAKAY (Introduced by James C. White), Boston, Mass.

The rate of entrance of normal constituents into cerebrospinal fluid (CSF) from blood is being studied in man, with minimal disturbance of the hydrodynamic system. Needles placed in one lateral ventricle, cisterna magna and lumbar subarachnoid space remain in position throughout the experiment. Following intravenous injection of 16 microcuries of Na²⁴ per kilogram, we withdraw at frequent intervals, samples of CSF not exceeding 0.2 cc. from each of the three points with concurrent blood samples. The final CSF pressure is not significantly altered from the initial level. Radioactive assay of specimens permits the drawing of satisfactory curves describing the rate of disappearance of Na²⁴ from blood serum and its rate of appearance in CSF at each of the three points sampled.

Studies have been carried out not only on individuals in whom the circulation of CSF was presumably normal, but also in patients with "hypertensive meningeal hydrocephalus," and in patients in whom a recent cerebral lobectomy for neoplasm had been carried out. Studies have been repeated after subsidence of the acute process in several patients.

A striking feature of the results has been the rapidity of appearance of Na²⁴ in the lateral ventricle as contrasted with a slower rate in the cistern and an extremely slow rate in the lumbar subarachnoid space. In both the normal and the abnormal individuals the concentration of Na²⁴ in the ventricle was three to four times that in the cistern at one hour, with an even greater differential prior to this time. In addition there appears to be an unexpectedly sluggish rate of flow and diffusion from the ventricles to

the cisterna magna, since a number of hours elapse before the concentrations at the two points become the same.

A Proplasma Activator from Mammalian Tissue. H. J. TAGNON and (by invitation) MARY L. PETERMANN, New York, N. Y.

The proteolytic enzyme plasmin is present in normal blood plasma as an inactive precursor called proplasmin. Activation can be brought about by treatment of plasma with certain organic solvents or by the action of streptokinase. In certain pathological conditions, for instance traumatic shock, the active enzyme may appear in the circulating blood. This results in digestion of fibrinogen and fibrin and may lead to uncontrollable hemorrhage. The mechanism of activation of proplasmin in shock is unknown.

The experimental evidence presented here indicates that an activator of proplasmin is present in tissue, notably in lung. By differential centrifugation in the cold, it was possible to separate from an aqueous extract a particulate fraction possessing most of the activity of the extract while an inhibitor which was present in the extract remained in the supernate, and could thus be separated from the activator.

The activator was not removed from the particles by several washings. The activator transformed proplasmin into plasmin even in the presence of the plasmin inhibitor of plasma. Optimal pH range extended from 6.0 to 7.2. The temperature optimum was 37° C. The amount of plasmin produced appeared to be proportional to the amount of activator and independent of the quantity of substrate (proplasmin). The activator lost its activity by incubation at 37° C. for 4 hours or at 56° C. for ½ hour. It could be preserved indefinitely in the frozen state.

The presence of a proplasmin activator, probably a kinase, in tissue may explain the fibrinolysis in exudates and the resorption of blood clots from tissues. Whether such an activator will provide an explanation for the fibrinolysis of shock remains to be demonstrated.

The Effect of Sodium Withdrawal upon the Body Weight of Normal Young Men. CAROLINE BEDELL THOMAS and (by invitation) EVELYN HOWARD and ARLENE ISAACS, Baltimore, Md.

A disturbance of salt and water metabolism in hypertensive patients has been described by Perera and Blood. They reported that, following 24 hours of sodium restriction, the elimination of salt and water from the body as reflected in loss of body weight was much less marked in patients with hypertension than in normal subjects. Their work raises two questions:

1. In a larger group of normal subjects, do some respond to sodium withdrawal like hypertensive patients?
2. If such individuals be found, is there any evidence that they will eventually have hypertension?

The body weights of 83 male medical students were observed following 24 hours of sodium restriction (sodium chloride 1 gram) while on a standard diet. Among 64 un-

selected students, a loss of 1.4 per cent of total body weight was the most frequent change observed. 47 lost 0.9 per cent or more, while 17 lost less than this amount, and in this respect resembled the hypertensive patients. Duplicate tests were carried out on 24 subjects, including 15 subjects showing the "hypertensive pattern" of response; results were consistent in 79 per cent of cases. A considerable proportion of normal young men, therefore, respond to sodium withdrawal with the "hypertensive" metabolic pattern.

A number of the unselected subjects had a history of hypertension affecting one parent, high normal resting blood pressure levels, a positive cold pressor test, or were overweight, and others selected because of these factors were included in the study. The correlation between these possible "prehypertensive" factors and the inability to lose weight following sodium withdrawal is discussed.

Correlation of Clinical Manifestations of Infection with the Elaboration of Hyaluronidase by Pathogenic Pneumococci. ROBERT T. THOMPSON and FRANCES E. MOSES (Introduced by Morton Hamburger), Cincinnati, Ohio.

Pneumococci isolated from the eighteen to twenty-four hour blood cultures of thirty patients were tested for the ability to elaborate hyaluronidase by inoculation into 0.20 per cent hyaluronic acid broth. Hyaluronidase elaboration was determined by the mucoprotein clot prevention test. Twenty-one patients had primary pneumococcal pneumonia; nine others had pneumonia associated with some other disease. Cultures from ten primary pneumonia patients failed to elaborate hyaluronidase; one of these patients died. Cultures from eleven primary pneumonia patients elaborated hyaluronidase; three of these patients died. Considering all thirty cases, the duration of infection before blood culture seemed related to hyaluronidase elaboration by the infecting pneumococci. Of the cultures from five patients who had been ill only one day, one elaborated hyaluronidase and four did not. Of the cultures from eighteen patients who had been ill two to five days, nine elaborated hyaluronidase and nine did not. Of the cultures from seven patients who had been ill for seven days or longer, six elaborated hyaluronidase and one did not.

In the twenty-one cases of primary pneumococcal pneumonia, there was no relation between the age of the patients or the number of lobes involved and hyaluronidase elaboration by the infecting pneumococci. However, of the cultures from eleven patients with blood urea nitrogen under 40 mgm. per cent, four elaborated hyaluronidase and seven did not. Of the cultures of eight patients with blood urea nitrogen above 40 mgm. per cent, five elaborated hyaluronidase and three did not. The blood urea nitrogen was not determined in two patients.

These findings indicate that pathogenic pneumococci are more likely to elaborate hyaluronidase in the infections of longer duration. In primary pneumococcal pneumonia hyaluronidase elaboration by infecting pneumococci is often associated with elevation of the patients' blood urea nitrogen.

The Influence of Streptomycin Dosage on the Pattern of Emergence of Drug Resistant Tubercle Bacilli in Patients with Pulmonary Tuberculosis. RALPH TOMPSETT (Introduced by Walsh McDermott), New York, N. Y.

Demerec has shown that the development of streptomycin resistance of staphylococci *in vitro* proceeds by a series of stepwise increases in the degree of drug resistance of the bacterial population. In contrast with the homogeneity of steps in penicillin resistance, the first-step streptomycin resistant strains as well as those of subsequent steps contained some organisms of the highest degree of resistance. It is manifestly impossible to eliminate these highly resistant bacteria by the highest concentrations of streptomycin attainable *in vivo*. Nevertheless, it is conceivable that elimination of intermediate steps might effect a significant reduction in bacterial population during the time required for the highest step resistant strains to assume predominance, and hence prolong the effective period of drug action. It seemed of interest, therefore, to determine if a similar stepwise pattern of resistance is demonstrable *in vivo*, and the influence of streptomycin dosage on its appearance.

Observations have been made on strains of tubercle bacilli obtained from sixty-four patients with pulmonary tuberculosis treated with streptomycin. In 33 patients who received 3.0 gm. of streptomycin daily, the streptomycin resistance of all but one of the strains of tubercle bacilli fell into two well-defined steps. All strains were highly sensitive to streptomycin (2.0 micrograms per ml.) prior to treatment. Strains obtained subsequently were found to remain at this level or to exhibit such a high degree of resistance that they were not inhibited by 100 micrograms per ml. of streptomycin.

In contrast, a high proportion of strains obtained from 31 patients given only 1.0 gm. of streptomycin daily exhibited degrees of resistance intermediate between these two extremes. As many as half of the strains obtained during certain periods were found to be streptomycin resistant to various degrees less than the maximum.

Effect of the Intravenous Injection of Vaccinia Virus on the Survival of Mice with a Transmissible Leukemia. JOSEPH C. TURNER and (by invitation) BARBARA MILLIKEN, New York, N. Y.

In the course of investigations designed to examine the influence of extraneous viruses on experimental neoplasms, it appears that the behavior of lymphatic leukemia 9417 in inbred mice may be modified by the introduction into the hosts of certain strains of living vaccinia virus. In five separate experiments extending over a period of some months, of 148 untreated control animals 13 (9%) survived for 30 days after the inoculation of leukemia and only 3 (2%) for 60 days or more. In the same experiments 187 mice received single or multiple intravenous injections of suspensions of vaccinia at varying intervals after the transplantation of the leukemia. Of these, 49 (26%) lived 30 days and 28 (15%) survived 60 days or more.

The variables involved are numerous and have not been fully resolved. The magnitude of the effect has so far appeared to be inversely proportional both to the acuteness of the leukemia and, perhaps paradoxically, to the virulence of the strains of virus. Thus, in the experiments noted above, vaccinia of low virulence, prepared from mouse-brain culture or frozen pulp (calf), were used. In other experiments highly virulent virus from rabbit-brain or egg-membrane have completely failed to influence the mortality of leukemic mice.

The mechanism of the observed effect remains uncertain; nor has it yet been settled whether the effect is determined by the infective particles themselves or some soluble component of the tissue suspension. Despite the difficulties attending the evaluation of findings in experiments with transmissible tumors, the point may be made that, as judged from an unequivocal end-point, survival, the behavior of a highly malignant neoplasm appears to have been modified in consequence of the introduction of a biological agent by the intravenous route at some time after the tumor may be assumed to have become established.

The Inheritance of Facioscapulohumeral Progressive Muscular Dystrophy; Variability in Expression in Human Inheritance as an Explanation of So-called "Anticipation." FRANK H. TYLER (Introduced by G. E. Cartwright), Salt Lake City, Utah.

A study has been made of a large kindred, certain members of which have facioscapulohumeral dystrophy. There are 1,249 individuals in six generations in the established pedigree. The inheritance is typical of a Mendelian dominant trait with complete penetrance and variable expressivity. Among the completely or nearly completely studied sibships which represent simple back crosses ($Dd \times dd$) there are 130 dystrophies and 143 normal individuals. The deviation from the expected 1:1 ratio is insignificant.

The disorder in the average patient is only slightly incapacitating. However, there is great variability in the severity of its expression in middle and old age. Even the patients with the more severe disabilities of the disease have had large families. This fact has permitted an enlightening comparison of the severity of the disease in the offspring and in the parent. This has shown that in certain families the children were more severely involved than the parents. In other families, the parents show the most marked changes.

In families in which diabetes mellitus or myotonia dystrophica occur, it has long been assumed that the disorder becomes progressively more severe in successive generations. This phenomenon has been called *anticipation* or *antedating*. Another explanation for the observed variation in these diseases is variability in the expression of the trait and the fact that in severe cases, beginning in adolescence, procreation becomes highly improbable. Comparison with the findings in facio-scapulohumeral dystrophy where large families can be studied, suggests that this is the true explanation rather than "anticipation."

The Use of Emission Spectrography in the Study of Metabolism of Metals in the Blood in Man. BERT L. VALLEE and JOHN R. LOOFBOUROW (Introduced by M. D. Altschule), Boston, Mass.

Emission Spectrography is based on the principle that high energy excitation of atoms causes them to emit light of characteristic wavelengths; each element has a typical spectral pattern which may be recorded photographically. This technique permits the simultaneous identification of practically all elements present in a given sample. Quantities as low as fractions of one microgram may be detected accurately. Quantitation of at least five or six elements simultaneously is possible.

Previous use of this technique resulted in identification of Zinc in leucocytes. Now in progress are studies of the distribution of elements in the fluid and corpuscular components of human blood. Studies have been made on Magnesium, Manganese, Copper, Strontium, Rubidium, Titanium and other metals regularly found in blood. Some of these elements, heretofore, have not been thought to be of biological significance.

The results of the present investigation are of interest in view of the known relation of metals to various enzyme systems present in erythrocytes and leucocytes. In some instances, the element is an integral part of the enzyme molecule such as in the case of iron in catalase, cytochromes, veridoperoxidase, zinc in carbonic anhydrase and copper in tyrosinase. In others, in vitro activation by various metallic ions has been found essential as exemplified by arginase, phosphatase and succinic dehydrogenase.

The significance of our findings in regard to the metal enzyme relationships will be discussed.

The Iron Metabolism and Acid Fragility of Erythrocytes in Paroxysmal Nocturnal Hemoglobinuria. PHILIP F. WAGLEY and MARGARET ADAMS (by invitation), and JOSEPH F. ROSS, Boston, Mass.

Two subjects (L. G. and L. T.) with paroxysmal nocturnal hemoglobinuria were given radioactive iron by parenteral injection and samples of their blood were taken at subsequent intervals. For a time the maximum possible age of the erythrocytes containing radioactive iron would correspond to the interval between the injection and the sampling. Washed erythrocytes derived from aliquots of blood taken at specified intervals after the injection of radioactive iron were subjected to hydrochloric acid hemolysis at a pH of 6.7-6.9 and determinations were made of the relative amounts of hemoglobin and of radioactive iron released. During a short period following injection, acid hemolysis released two to three times more radioactive iron from the red cell mass than could be accounted for by release of hemoglobin.

Most of this radioactive iron released by acid hemolysis was not loosely bound ("easily splittable iron"); 73-96 per cent of the radioactivity was precipitated with the proteins by trichloroacetic acid.

These observations have been considered in light of two possibilities: (1) the susceptibility of the red blood

cell to acid hemolysis may vary with age of the cell, or (2) all of the radioactive iron released by acid hemolysis is not in hemoglobin, some being in other protein bound form(s). The implications of these possibilities will be discussed.

The Effect of Auricular Fibrillation on the Coronary Circulation. RENÉ WÉGRIA and (by invitation) RICHARD P. KEATING, HENRY P. WARD and CHARLES W. FRANK, New York, N. Y.

Forty-five bouts of auricular fibrillation induced in twelve dogs were studied as to their effect on the mean arterial blood pressure and coronary flow.

At the onset of auricular fibrillation, a marked drop in blood pressure and coronary flow occurs. Then, within a few seconds, both blood pressure and coronary flow return toward their control levels, but whereas the coronary flow may, at least temporarily, return to or even rise above its control level, the blood pressure very seldom reaches it. As soon as fibrillation stops, both coronary flow and blood pressure rise above control levels, then come down progressively to their control level, but the blood pressure may come back to its control level before the coronary flow. The mechanisms and significance of the cardiovascular reactions observed will be discussed.

Growth Forms of Common Bacteria Indistinguishable from Pleuropneumonia-Like Organisms. HOWARD J. WEINBERGER and LOUIS DIENES (Introduced by J. H. Means), Boston, Mass.

The authors will present additional evidence indicating that many commonly occurring bacteria can survive and multiply in a peculiar form not recognizable by the usual bacteriological methods.

Freshly isolated strains of many bacillary species transferred to appropriate media containing varying concentrations of penicillin undergo a peculiar transformation which results in the development of colonies indistinguishable from those of the Pleuropneumonia group. Strains of Typhoid, Salmonella, Shigella, H. influenzae, Proteus, Bacteroides, Flavobacterium, Streptobacillus moniliformis, and a Gram positive spore bearing bacillus exhibited this phenomenon. In Salmonella, Proteus, Bacteroides and Streptobacillus these Pleuropneumonia-like (L) forms can be made to revert to the usual bacillary forms indicating that they are growth forms of the bacteria despite the marked differences in their morphology, staining reactions, physical properties, and growth and reproductive characteristics.

The effect of penicillin is not specific. Similar transformation occurs under other "untoward" influences including autolysis of the cultures. Exposure of typhoid bacilli to fresh human serum also has resulted in the development of typical L colonies.

The Pleuropneumonia group is responsible for important animal diseases. In humans Pleuropneumonia-like organisms have been recovered from prostatic, urethral and vaginal secretions, bladder and kidney urine, joint fluid, empyema fluid, paronychia and peritoneal abscesses and sputum.

The nature of these organisms is not fully understood and in most cases the relation of the organisms isolated from pathological processes to a parent form has not been established. The pathological significance of bacteria in the Pleuropneumonia-like form warrants intensive study. Such organisms have been observed under conditions similar to those prevailing in the body. In light of the widespread therapeutic use of penicillin and the frequent incorporation of penicillin in culture media, it is possible that the incidence of Pleuropneumonia-like organisms will increase.

Studies of the Influence of Penicillin on the Immune Reactions in Streptococcal Pharyngitis. LOUIS WEINSTEIN and (by invitation) LOUIS BACHRACH and THOMAS S. PERRIN, Boston, Mass.

A group of 225 patients with pharyngitis due to the beta-hemolytic streptococcus was treated with penicillin given in a dose of 15,000 units intramuscularly every 3 hours for 10 days. Serial examinations of their serums for antistreptolysin, antistreptokinase, anti-M, and anti-C substance antibody and the "phase" reacting material of Coburn, at weekly intervals for a month or more revealed that there was a marked reduction in the ability to produce all of these antibodies. In contrast to the 75-85 per cent incidence of antistreptolysin and the 25-35 per cent incidence of antistreptokinase in control untreated patients, of those given penicillin only about 12 per cent developed significant antistreptolysin and/or antistreptokinase titers. In the treated individuals who showed an increase in either or both of these antibodies, the height of the titer attained was considerably lower than in the average control patient. None of the treated group developed any anti-M or anti-C substance antibody and the "phase" reactions indicated the lack of value of this test as a diagnostic aid in rheumatic fever. About 7 per cent of the treated individuals developed rheumatic fever while approximately 6 per cent showed evidence of a varying degree of glomerular nephritis; of these patients, only about $\frac{1}{3}$ had a rise in antistreptolysin or antistreptokinase in the blood.

When the penicillin treatment schedule was changed to administration every 8 hours either intramuscularly or orally, the number of individuals showing significant antistreptolysin titers increased remarkably. Thirty-two per cent of 103 patients given 100,000 units intramuscularly every 8 hours showed an increase in this antibody. Exhibition of penicillin by mouth on an 8-hour schedule showed an even lesser tendency to inhibit antibody formation and in a group of 241 patients given the drug in doses varying from 50,000 to 800,000 units, from 40 to 80 per cent showed an increase in antistreptolysin. These differences in antibody formation could not be correlated with persistence or recurrence of streptococcal infection since the vast majority of the patients were rid of their organisms in 24-48 hours after therapy was instituted. That the increased incidence of antibody formation may be due to longer persistence of Streptococcus in the pharynx is suggested, however, in the group receiving 500,000 units of penicillin orally every 8 hours since, in these pa-

tients, recurrence of the organisms in the pharynx was common after treatment was stopped. A small number of individuals receiving oral penicillin showed a rise in the anti-M substance antibody.

The Fate of Transfused Leukocytes. AUSTIN S. WEISBERGER (by invitation), ROBERT W. HEINLE and (by invitation) JOHN P. STORAASLI and RICHARD HANNAH, Cleveland, Ohio.

Elevation of the leukocyte count following whole blood transfusions does not occur even in severely leukopenic recipients. A study of this phenomenon was undertaken. Concentrated suspensions of leukocytes were obtained from the peritoneal cavity of rabbits by distending their abdomens with physiologic saline. If radioactive phosphorus (P^{32}) was administered previously in doses of 1 millicurie, the cells obtained were radioactive. The fate of such transfused cells was studied by determining the radioactivity of tissues of recipient rabbits.

The peritoneal fluid was collected, centrifuged and washed. Practically all of the P^{32} was fixed in the cells. These were resuspended in Tyrodes solution and transfused into the same or other rabbits.

Following the intravenous injection of radioactive or non-radioactive leukocytes, an initial increase of blood leukocytes never occurred. Instead, a profound leukopenia developed usually within 1 to 5 minutes. In more than half the animals a subsequent leukocytosis occurred after 4 to 6 hours. In 5 rabbits sacrificed during the leukopenic stage, the distribution of radioactivity was: lung, 45.4 per cent; liver, 20.7 per cent; spleen, 1.0 per cent. In marked contrast, the distribution following injection of inorganic P^{32} was: lung, 1.3 per cent; liver, 11.9 per cent; spleen, 0.33 per cent. Following intra-aortic injection of radioactive leukocytes into 5 rabbits, the distribution of radioactivity was: lung, 30.5 per cent; liver, 17.8 per cent; spleen, 0.35 per cent. Following disappearance of the leukopenia (4 to 6 hours), the distribution in 5 rabbits was: lungs, 19.1 per cent; liver, 34.9 per cent; spleen, 3.4 per cent.

These findings suggest that the lung plays an active role in controlling the blood leukocyte level. Since cell-free aqueous extracts of leukocytes produce a similar profound leukopenia, the arrest of leukocytes in the lungs represents more than a simple filtering of foreign bodies.

Effects of Infusion of Albumin on the Excretion of Water and Electrolytes in Normal Subjects. LOUIS G. WELT and JACK ORLOFF (Introduced by John P. Peters), New Haven, Conn.

During infusions into normal subjects of 100 grams of a 25 per cent solution of salt-poor albumin the rate of excretion of sodium decreases. There is no significant alteration in water excretion. These changes are associated with an increase in plasma volume. They are not correlated with the degree of change in total protein or albumin concentrations in the serum nor with a significant change in endogenous creatinine clearance.

Administration of a 10 per cent solution of albumin resulted in an increase in plasma volume and a definite de-

crease in the rate of excretion of sodium and water. In contrast, when albumin was administered as a 4 per cent solution water excretion rose strikingly and sodium excretion questionably. This reaction was less marked when a 5 per cent solution was administered.

It appears that when albumin is infused in normal subjects in concentrations with a higher colloid osmotic pressure than that of serum the rate of water and sodium excretion diminishes below that obtained with iso-osmotic albumin infusions. When the plasma volume is expanded, but the colloid osmotic pressure remains normal the kidneys respond in such a manner as to correct over-hydration; but when expansion of plasma volume is accompanied by excessive colloid osmotic pressure their response is adjusted to correct dehydration. Gradations of these reactions elicited by varying the concentrations of injected albumin suggest that the responses are controlled by the balanced action of two forces, colloid osmotic pressure and plasma volume.

It is also possible that a decrease in interstitial fluid volume in normals initiates a mechanism that increases the reabsorption of sodium and water; and an increase in plasma volume unassociated with a decrease in interstitial fluid volume provokes a diuresis.

A Comparison in the Same Individual of the Nitrogen Loss Following Surgery with that Produced before Operation by an Identical Feeding Program. SIDNEY C. WERNER, New York, N. Y.

Twenty-eight patients on approximately adequate diets in terms of calories and protein have been given a reduced diet similar to that usually given post-operatively, both before and after the procedure. The resultant alterations in nitrogen balance have been compared. No significant increase in negative nitrogen balance occurred after cholecystectomy, inguinal or extensive ventral hernia repair, provided constant feeding was maintained through the operative day and subsequently.

The data obtained suggest that most of the work during the war concerning the effect of trauma or disease on nitrogen balance cannot be interpreted as indicating the role of injury. First, the preceding dietary intake was often not known. Second, a constant intake of calories and protein was not maintained from the moment of trauma. Third, the increased demands for calories resulting from fever have not been taken into account, in most studies.

Since no changes in nitrogen balance after operation have been found which could not be accounted for on the basis of inadequate calories, a review of the typhoid fever work on "toxic destruction of proteins" has been made. Here too, adequate provision of calories produced nitrogen equilibrium at the height of disease, a finding similar to the war period findings in this and other laboratories on the effect of increased protein, or calorie and protein, intake after injury or operation. The one study suggesting that an excess of calories is needed in typhoid fever to restore nitrogen equilibrium is vitiated by the fact that the patients lost weight on a theoretically adequate diet.

It is thus suggested that the "catabolic response" or "toxic destruction of proteins" is probably the result of

lack of provision of adequate calories, protein, or both, and not of unusual body mechanisms being brought into play; or if such effects are present, that, divorced from under-nutrition, they are not highly significant.

Antidiuresis and Renal Vasoconstriction Following Venous Congestion of the Limbs in Normal, Hypertensive, and Splanchnicectomized Subjects. ROBERT W. WILKINS, (by invitation) JAMES W. CULBERTSON, BELTON A. BURROWS, CLARENCE M. TINSLEY and WALTER E. JUDSON, and CHARLES H. BURNETT, Boston, Mass.

When the legs of supine subjects were congested by blood pressure cuffs inflated on the thighs at less than diastolic pressure for 10 to 20 minutes, there was usually little change in arterial pressure or pulse rate, and little effect on renal circulation or function until after the cuffs were released. Ten to twenty minutes after the release of the congesting cuffs there was a marked antidiuresis (as much as 90 per cent), a decrease (25 to 60 per cent) in renal plasma flow (PAH) and filtration rate (inulin, mannitol), and a reduction of sodium, potassium and chloride excretion (as much as 60 per cent). In 10 to 20 minutes the changes in renal circulation and electrolyte excretion had usually disappeared, but the antidiuresis persisted for at least 40 minutes.

Similar renal functional and circulatory effects followed venous congestion of the limbs of hypertensive subjects before and after lumbodorsal sympathectomy.

These results appear significant in connection with the various mechanisms of water and salt retention and the disturbances of renal circulation in venous congestive myocardial failure. They indicate that venous congestion of the limbs, and possibly of other peripheral areas, may contribute to the causes of reduced renal plasma flow and excretion of water and salt in this condition. Apparently these renal disturbances may persist for some time after the relief of venous congestion. They are not necessarily preceded by changes in renal arterial or venous pressure, and are not mediated over the splanchnic sympathetic nervous system since they are present after splanchnicectomy. Possibly they are mediated through humoral mechanisms.

The Application of a Strain Gauge Manometer, a Modified Ear Oximeter and Whole Blood Cuvette Oximeter to the Technic of Cardiac Catheterization. EARL H. WOOD, EDWARD LAMBERT and HOWARD B. BURCHELL. (Introduced by Charles F. Code), Rochester, Minn.

A strain gauge manometer (Statham Model P6-250-15D) coupled without amplification to sensitive galvanometers affords one of the most accurate and simple means of recording pressure through a cardiac catheter. Uniform sensitivity to sine wave variations in pressure of from 0 to 28 cycles per second may be obtained through a cardiac catheter if proper electrical and mechanical damping are used. This is superior to the dynamic response obtained with a Hamilton manometer (natural frequency: 120 cycles per second). The strain gauge manometer is connected to (1) a visual indicating galvanometer utiliz-

ing a red light thus permitting continuous monitoring of pressures during roentgenoscopy and (2) an oscillographic galvanometer located in an adjacent recording room which permits simultaneous and continuous photographic recordings of the variations in pressure transmitted through the catheter. It is recognized, however, that the physical characteristics of the catheter and the pressures generated within its lumen by the acceleration and deceleration of the fluid column associated with the movements of the catheter imparted by the heart beat obviate the possibility of obtaining uniformly reliable tracings of intracardiac pressure with manometers attached to the external end of the catheter.

Variations in arterial saturation are recorded continuously on the oscillograph and monitored simultaneously from a visual reading scale by means of a modified ear oximeter.

The oxygen saturations of samples of blood withdrawn from the catheter are recorded and monitored similarly with a whole blood cuvette oximeter. The electrocardiogram and respiration are recorded simultaneously.

Immediate correlation of oxygen saturation of samples of blood withdrawn from the catheter with associated observations of pressure, arterial saturation, and location of the tip of the catheter (roentgenoscopy) greatly expedites the procedure. The probable diagnosis was apparent prior to withdrawal of the catheter in the majority of cases in which analysis of all data ultimately proved sufficient for such a decision to be made.

The Chemoprophylaxis of Scrub Typhus in Volunteers. T. E. WOODWARD and H. L. LEY JR. (by invitation), and J. E. SMADEL, Washington, D. C.

Two field trials were conducted in Malaya in which 75 volunteers were exposed in hyperendemic areas of scrub typhus. Thirty-four of these individuals received Chloromycetin prophylactically for a total period of three weeks during and following exposure. They did not show clinical evidence of scrub typhus throughout the period of prophylaxis or the ensuing week. However, scrub typhus developed in 15 volunteers in the prophylactic groups of the two trials 5 to 14 days after drug was discontinued. Although the attack rate among the volunteers in the two field trials varied markedly, there was no essential difference in the ultimate infection rates among the controls and those given prophylaxis in each test.

Scrub typhus, when it developed among volunteers in the prophylactic group, was not significantly different from the disease in the controls except for the absence of eschar formation.

Relapses were prominent features of the disease in the volunteers of both prophylactic and control groups. These had not been observed previously in untreated cases of scrub typhus or in naturally occurring cases which were treated with chloromycetin. Fifty-four per cent of the 37 persons in the two trials who contracted scrub typhus suffered one or more relapses. Various factors probably contributed to this phenomenon.

Prolonged administration of chloromycetin as a prophylactic measure and its use in the treatment of the initial

attacks of scrub typhus as well as the relapses indicated that the drug is of low toxicity for man, and that drug-fast strains of *R. tsutsugamushi* are not readily produced.

Experimental Production of Hemolytic Disease in Newborn Dogs. LAWRENCE E. YOUNG and (by invitation) DONALD M. ERVIN, RICHARD M. CHRISTIAN and R. WENDELL DAVIS, Rochester, N. Y.

Isohemagglutinins of 4 different specificities have been demonstrated in sera of dogs following transfusions of dog erythrocytes containing antigenic factors lacking in their own cells. Since the behavior of one of these antibodies is in some respects similar to that of Rh antibodies, dog antisera having this specificity have been tentatively designated "anti-Do," and dog cells have been classified as "Do-positive" or "Do-negative" depending upon their reaction with such sera.

Hemolytic disease has been produced in Do-positive puppies born to a Do-negative dam immunized by transfusions of Do-positive cells before mating with a Do-positive sire.

In the first litter investigated, erythrocytes of 4 affected Do-positive whelps were agglutinated by high dilutions of anti-dog-serum rabbit serum and were also agglutinated when suspended in undiluted normal dog serum, presumably because the cells were coated with Do-antibody. Plasma from 4 unaffected Do-negative whelps in the same litter agglutinated the sire's cells, but iso-antibodies were not detectable in the plasma of the affected Do-positive puppies. The dam's breast milk agglutinated the sire's erythrocytes but absorption of iso-antibody from milk by the puppies could not be demonstrated.

The degree of anemia and icterus varied markedly among the affected whelps of the same litter. Erythrocytes of all of the Do-positive puppies, however, showed increased osmotic fragility, and reticulocytes and nucleated red cells were more numerous in venous blood of the affected puppies. Autopsy of a severely anemic whelp and of a normal litter mate revealed more marked erythropoiesis in liver, spleen and marrow of the affected animal.

Observations thus far completed suggest that studies on hemolytic disease in newborn dogs may aid in clarifying certain aspects of the comparable human disorder, and that controlled investigations on large litters sired by heterozygous males may be especially productive.

Intrathoracic Pressure Change as an Aid in the Anatomic Localization of Murmurs and Other Sounds of Cardiovascular Origin. HARRY F. ZINSSER, JR. (by invitation) and CALVIN F. KAY, Philadelphia, Pa.

Certain commonly used diagnostic techniques are based on the relationship of murmur intensity to rapidity and volume of blood flow. By exercise, amyl nitrite and other means, circulatory velocity is increased to accentuate murmurs. If blood flow could be altered *differentially* in the lesser and greater circulations, the time of murmur accentuation should provide a clue to its anatomic origin. Such changes in circulatory dynamics occur in the relaxation period immediately following voluntary straining.

During straining, venous blood return is decreased. The right heart output falls, the pulmonary reservoir is depleted, and systemic output falls. When intrapulmonic pressure returns to atmospheric level, venous blood rushes first into the right heart, causing vigorous pulmonary artery pulsations and restoring the lesser circulation. Left heart output and aortic pulsations become maximal only after the pulmonary blood reservoir is restored.

It was predicted, therefore, that murmurs should become faint during straining and gain intensity after relaxation. Murmurs of right heart or pulmonic origin should become intense immediately in the post-straining period, while return of left sided or peripheral murmurs should be delayed.

Studies were undertaken with combined phonocardiographic, electrokymographic, and electrocardiographic techniques upon subjects with murmurs of either known or unknown origin. Variations in intrathoracic pressure produced by straining against a mercury manometer were recorded with strain-gauge attachment.

Recordings bear out the predicted results. Murmurs were loudest either early, associated with maximal electrokymographic pulmonary artery pulsations; or late, coinciding with maximal aortic pulsations. Certain patients fail to produce effective straining. Where straining was effective, the method successfully differentiates known right sided from left sided murmurs. In patients with murmurs of unproven type, equally decisive results seem significant by deduction. Alterations of other cardiac sounds also occur, similarly suggesting the site of production.

THE ELIMINATION OF PENICILLIN G IN BILATERALLY NEPHRECTOMIZED DOGS^{1,2}

By WILLIAM H. ANDERSON³ AND ROLF BRODERSEN⁴

(From the Department of Medicine, University of Chicago)

Rammelkamp and Keefer (1) found that only about 60 per cent of intravenously administered penicillin could be recovered from the urine of man. This finding has been confirmed by later reports, although the recovered amounts vary from 40 to 99 per cent (2).

This paper deals with the mechanism of the elimination of penicillin in bilaterally nephrectomized dogs.

Diffusion of Penicillin from Blood to Tissues

A dog, in which the elimination of penicillin⁵ had been blocked by bilateral nephrectomy and ligation of the cystic and common bile ducts, was given an intravenous injection of 25,000 units/kg. of crystalline penicillin G. Blood samples were taken from another vein at intervals from two minutes to 10 hours after the injection. The serum concentrations of penicillin were determined using a serial dilution technique.

In Figure 1, the serum penicillin concentrations have been plotted on a logarithmic scale as a function of time after the injection. The penicillin concentration decreases rapidly during the first hour but thereafter very slowly. For the time being we shall consider only the first portion of the curve. We may assume that this initial decrease was due to diffusion of penicillin from the blood stream into the tissues.

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

² This investigation was supported (in part) by a research grant from the Antibiotics Study Section of the Division of Research Grants and Fellowships of the National Institutes of Health, U. S. Public Health Service and (in part) by the A. B. Kuppenheimer Foundation and the Douglas Smith Foundation of the University of Chicago.

³ Research Fellow, U. S. Public Health Service.

⁴ Douglas Smith Foundation Fellow in Medicine.

⁵ The crystalline penicillin was supplied by Abbott Laboratories, Commercial Solvents Corporation, Lederle Laboratories, and Schenley Laboratories, Inc.

One can imagine this process as taking place through a thin membrane from one phase to another. At the time $t=0$, all penicillin is in the one phase having the concentration c_0 . If the concentration in this phase is c_t at the time t and c_∞ when equilibrium is established we have:

$$\ln (c_t - c_\infty) = \ln (c_0 - c_\infty) - Kt \frac{c_0}{c_0 - c_\infty}, \quad (1)$$

where \ln denotes the natural logarithm and K is the velocity constant.

From the data in Figure 1, K is found to be 5 1/hours. The curve in the figure is drawn according to equation (1), this value being used for K and allowance being made for the inactivation in the later part of the experiment. Agreement is found between the calculated curve and the experimental points. The value, 5 1/hours, for K was confirmed in another experiment of similar nature as the one depicted in Figure 1.

If there were no further elimination of penicillin from the blood, the concentration would decrease to a constant value which would be reached when diffusion equilibrium was established. This concentration may be found by drawing the straight line representing the inactivation back to intersection with the axis of the ordinate which, in this case, was 143 units/ml. of serum.

FIG. 1. THE SERUM PENICILLIN CONCENTRATION AS A FUNCTION OF THE TIME AFTER A SINGLE INTRAVENOUS INJECTION

The inactivation has been partially blocked by bilateral nephrectomy and ligation of the cystic and common bile ducts.

The equilibrium concentration was determined in a number of experiments and collected in Table I. In the last column of this table are the ratios between c (serum concentration of penicillin at equilibrium) and the dose of penicillin per gram of dog. In 16 experiments this ratio was found to be larger than unity; that is, the penicillin did not distribute equally throughout the tissues of the dog; but was present in a higher concentration in the plasma than in the remainder of the dog. The average ratio was about four times as great, when diffusion equilibrium was established. The reason for this is not clear.

TABLE I

The serum concentration (c_{∞}) of penicillin after diffusion equilibrium has been established with the tissues

Values are corrected for any elimination or inactivation of penicillin taking place.

Dose units/kg.	c_{∞} units/ml.	c_{∞} units/ml. dose units/gram of dog
85,000	400	4.7
80,000	250	3.1
30,000	130	4.3
25,000	90	3.6
25,000	70	2.8
25,000	80	3.2
25,000	100	4.0
25,000	85	3.4
25,000	100	4.0
25,000	110	4.4
25,000	80	3.2
25,000	100	4.0
25,000	140	5.6
14,000	60	4.3
14,000	60	4.3
7,000	20	2.9
Average.....		3.9
Maximum.....		5.6
Minimum.....		2.8

From Table I we obtain the formula:

$$\text{Serum penicillin concentration} = 4 \times \text{amount of penicillin per gram body weight.} \quad (2)$$

—provided that diffusion equilibrium is present. This equation shows the relationship between the amount of penicillin present in the body and the serum concentration. This could be used to estimate the former when the latter is known. The formula has been established for the blood concentrations between 20 and 400 units/ml. and may not be valid for smaller concentrations.

The Renal and Extra-Renal Elimination

Blood serum concentrations of penicillin were determined at intervals after a single intravenous injection in a number of normal dogs. If allowance is made for the diffusion equilibrium to be established, it was found that the logarithm of the

concentration decreased as a linear function of time (first order reaction). This relationship was found to be valid from the initial concentration of about 100 units/ml. to 1 unit/ml. A curve demonstrating this relationship is shown in Figure 2.

Bilateral nephrectomy was performed in three dogs which were then given a single intravenous injection of penicillin. The relationship between serum concentration and time showed that these dogs were still able to eliminate penicillin from the blood stream, although, as was to be expected, at a considerably lower rate (Figure 2). Here also, the inactivation took place as a reaction of the first order. The rate of elimination was, as an average, found to be one-fourth as rapid in the nephrectomized as in the normal dogs. This means that approximately three-fourths of the penicillin was eliminated through the kidneys and one-fourth somewhere else. From the variable velocities obtained in normal and nephrectomized dogs, a considerable variation is to be expected in the fraction of penicillin inactivated extra-renally.

The Site of the Extra-Renal Elimination

The rate of elimination was not significantly changed by the removal of the intestine from the

FIG. 2. ALL DOGS WERE GIVEN 25,000 UNITS OF PENICILLIN PER KILOGRAM IN A SINGLE INTRAVENOUS INJECTION

ligament of Treitz to within an inch of the anus, nor by the removal of the stomach and ligation of the common bile duct. This showed that, in these dogs, the intestinal tract was not the primary site of the extra-renal elimination, as suggested by the findings of Reid (3).

The serum penicillin concentration remained constant, within the limits of experimental error, following complete evisceration; thus the site of the elimination was somewhere in the viscera.

A two stage hepatectomy and bilateral nephrectomy were performed in a dog. Here too, no inactivation could be shown after the equilibration of penicillin between the blood stream and the tissues. In another dog, both kidneys and all the viscera except the liver were removed. The hepatic artery was left intact by dissecting away the hepatico-duodenal ligament. The portal vein and the common bile duct were ligated and the gall bladder left in connection with the biliary system. This dog eliminated penicillin at a rate very similar to the dogs in which only bilateral nephrectomy was done. It could be concluded that the liver was responsible for the extra-renal elimination of penicillin in these dogs.

The velocity constants were found from the obtained curves by the formula:

$$K = -\frac{\ln(c_1/c_2)}{t_1 - t_2} \quad (3)$$

The results, in reciprocal hours, are found in Table II. The velocity constant indicates the relative decrease in penicillin concentration, or total amount of penicillin, per hour.

The Mechanism of the Hepatic Elimination of Penicillin

In two dogs the kidneys were removed, the cystic and common bile ducts were ligated twice and cut. Similar curves were found in both dogs; one curve is shown in Figure 3. It was noted that a certain elimination of penicillin seemed to occur during the first 10 hours; however, the rate of elimination decreased after this to a very low value. Thus, penicillin was still present in appreciable amounts 70 hours after the intravenous injection. The final rate of elimination here was only 4 per cent of the normal rate. This finding seemed to indicate that the penicillin was excreted in the bile rather than destroyed by the liver; if

The Slow Elimination after Bilateral Nephrectomy and Ligation of Cystic and Common Bile Ducts

FIG. 3. THE ELIMINATION DURING THE FIRST 10 HOURS MAY BE DUE TO EXCRETION OF PENICILLIN CONTAINING BILE INTO THE BILIARY SYSTEM TO THE POINT OF DISTENSION

The slower inactivation throughout the 70 hours of the experiment can be explained by the destruction of penicillin due to the alkalinity of the bile.

FIG. 4. THE LINES SHOW THE INACTIVATION, AT THE GIVEN pH VALUES AS CALCULATED FROM THE DATA OF BRODERSEN (4), IN GOOD AGREEMENT WITH THE EXPERIMENTAL POINTS

The two samples of bile were obtained from the gall bladder (pH 6.00) and from a common duct fistula (pH 8.29).

The pH values were determined electrometrically by comparison with 0.01 *m.* HCl + 0.5 *m.* NaCl (pH 2.00). The hydrogen ion concentrations were found to be independent of temperature in the range of 20 to 40° C.

so, the initial drop in serum concentration might be due to excretion of bile into the biliary system to the point of distention. However, it appeared still possible that destruction may have taken place in the liver, but that liver function was impaired by the biliary obstruction.

In another nephrectomized dog, the common bile duct was cannulated and the secreted bile collected hourly after an intravenous injection of penicillin. Very high concentrations of penicillin were found in the bile samples. The total amount recovered in the bile was 80 per cent of the injected penicillin. It could be concluded that, at least in this dog, the main part of the extra-renal elimination took place as excretion in the bile.

Inactivation by Bile In Vitro

A sample of dog's bile (pH 8.29), obtained from a fistula, was mixed with penicillin and incubated at 37° C. A rather slow inactivation was found to take place. Another sample drawn from the gall bladder (pH 6.00) did not inactivate penicillin at a demonstrable rate. This suggested that the inactivation was due to the alkalinity of the fistula bile. The rate of inactivation to be expected in this case was calculated (4) and found to be consistent with the experimental values

(Figure 4). The rate of inactivation in the bile can thus be calculated at known values of temperature and hydrogen ion concentration on the basis of the known destruction rate by alkali.

At the highest pH values found in the bile (8.65), the rate of inactivation found in the dogs with ligated bile ducts (Figure 3) could readily be accounted for as taking place in the bile standing in the intra-hepatic ducts.

The Relationship of Penicillin Concentrations in Serum and Bile

In Figure 5 are plotted the concentrations of penicillin in cannulated bile and in blood serum taken simultaneously from a nephrectomized dog. There was a constant ratio between the two concentrations, the bile containing 130 times as much penicillin per ml. as the serum at serum concentrations ranging from 100 to 5 units/ml. This ratio was found to vary considerably. In seven experiments carried out in two dogs, values ranging from 10 to 330 were obtained. From the figures in Table III it is seen that the high ratios generally were found at high pH values in the bile and the low ratios at the low pH values.

FIG. 5. THE BILE IS SEEN TO CONTAIN ABOUT 130 TIMES AS MUCH PENICILLIN PER MILLILITER AS THE SERUM, INDEPENDENT OF THE SERUM CONCENTRATION

Storage of Penicillin in the Gall Bladder

In a normal dog, a cannula was placed in the gall bladder and the common bile duct ligated in order to close the outlet from the gall bladder. The bile was drawn from the gall bladder, mixed with 100,000 units of penicillin and reinjected. Every hour the volume of bile in the gall bladder was determined and a small sample taken out for penicillin assay. The total amount of penicillin found in the gall bladder is shown in Figure 6. The pH values were determined at the same time and from these the spontaneous inactivation calculated as shown by the curve. The difference between this curve and the points demonstrates

RESORPTION AND INACTIVATION OF PENICILLIN IN THE GALL BLADDER

FIG. 6. THE CURVE INDICATES THE CALCULATED INACTIVATION

The experimental points are seen to deviate relatively little from this curve, indicating that only a slow resorption of penicillin takes place from the gall bladder.

the resorption from the gall bladder. Within the four hours of the experiment the resorbed amount is seen to be rather small. That a certain resorption does take place was shown by the fact that penicillin was present in the urine of the dog.

SUMMARY AND CONCLUSIONS

Bilaterally nephrectomized dogs were found to eliminate penicillin at a considerable rate from their blood stream after an intravenous injection. This process took place even if the intestines were removed, whereas no inactivation could be demonstrated after complete evisceration or hepatectomy. A major part of the penicillin was found to be excreted in the bile. A certain inactivation took place in the bile, especially when it was strongly alkaline. The remaining portion went either to the gall bladder, where only a slow resorption took place, or to the intestine, where it was partially resorbed and partially inactivated.

Caution must be exercised in drawing generalized conclusions from these results. Since the nephrectomized dogs do not eat, it seems possible that normal dogs might inactivate certain amounts of penicillin in their intestine because of a greater excretion of digestive juices.

STUDIES ON HYPERSENSITIVITY TO PENICILLIN. I. INCIDENCE OF REACTIONS IN 1303 PATIENTS^{1, 2}

By MARK H. LEPPER, HARRY F. DOWLING, JAY A. ROBINSON, THOMAS E. STONE, ROBERT L. BRICKHOUSE, ESTON R. CALDWELL, JR.,
AND RICHARD L. WHELTON

(From the George Washington University Medical Division, Gallinger Municipal Hospital, and the Department of Medicine, George Washington University, Washington, D. C.)

Although penicillin is a relatively safe drug, many reactions, including three deaths (1-3), have been reported following its administration. Most of these reactions appear to be allergic in origin, even though the nature of the antigen has usually not been determined. During the years that penicillin was being purified many reactions were considered to be caused by impurities, particularly when the reaction was specific for a particular lot. When slowly absorbable preparations became available it seemed important to determine whether administration in this form increased the incidence of reactions. We have undertaken a study to determine the reaction rate to crystalline penicillin in aqueous solutions and to slowly absorbable forms as seen in ordinary hospital practice as well as factors influencing the incidence of such reactions and the nature of the antigen involved. In the present paper we are reporting the incidence of reactions which we have found and some of the factors believed to be important in determining the reaction rate. Studies on skin tests with penicillin oil and beeswax will be reported elsewhere (4).

METHOD

The method of this study was to observe daily all patients being treated with a preparation containing penicillin. Before treatment was initiated the patients were questioned regarding previous courses of penicillin and previous allergic reactions. A physical examination was then performed and the type of preparation, the dose, and the lot number of the penicillin employed were recorded. At least once a day each patient was examined and questioned closely regarding signs and symptoms of allergic reactions and of reactions at the site of injection. At

the start of the study it was anticipated that most of the patients would be given a second course of penicillin after an interval of several days in order to bring out latent sensitivities. It soon became apparent that this procedure produced very few allergic reactions so that the method was abandoned. As a result, in order to demonstrate statistically significant differences between the various preparations of penicillin we were forced to rely mainly on the observation of a large number of patients receiving each preparation.

The diagnosis of allergic reactions, where no confirmatory data were available (such as a positive reaction to a skin test or to a second course), was made on clinical grounds by the appearance of the reaction when penicillin was being administered and its disappearance shortly after the antibiotic was discontinued and by the fact that no other allergen could be indicted. Patients who developed reactions typical of serum sickness shortly after penicillin administration were considered penicillin reactors if no other reasons were found for such a reaction.

RESULTS

A total of 1303 patients who were under treatment for various infections were followed in this manner. As shown in Table I, 598 received aqueous crystalline penicillin, 557 were given crystalline penicillin in oil and beeswax, and 148 received procaine penicillin in oil. The incidence of allergic reactions in these groups was 1.2, 2.7, and 1.4 per cent respectively. The rates were significantly higher for the oil and wax group than for the aqueous group. There were not enough patients who received procaine penicillin to make the difference between this and the other groups statistically significant. An analysis of the effect of the size of the dose used on the incidence of reactions revealed that in the oil and beeswax and in the procaine penicillin groups, where maximum dose employed was only four times the minimum dose, no difference in the reaction rate with moderate and low doses was found. In the aqueous penicillin group, however, many of the doses used were ten or more times the usual doses employed. Thus, if the patients receiving 500,000

units or more every two hours are compared to those receiving less than this amount, reaction occurred in four among 51 patients (7.8 per cent) and in three among 547 patients (0.6 per cent) respectively. This difference is statistically sig-

nificant when tested by the chi square test. Table II compares these rates with similar figures obtained by us for one of the sulfonamides (sulfamerazine). There is a trend in our figures which indicates that the incidence of reactions increased as the duration of therapy was prolonged although there are too few reactions to be certain of this point.

Two factors found to be of significance in the

incidence of reactions to penicillin are a previous allergic history and the previous administration of penicillin. Tables III and IV illustrate these data. Reactions believed to be caused by penicillin itself and by the vehicles used (as determined

by second courses and/or skin tests) are listed separately. The patients in this, the controlled series, who showed reactions to penicillin are listed alone and are also included in the total group of reactors to penicillin. This total includes, in addition, the penicillin reactors whom we observed from all other available sources. In the controlled group there is a significantly greater reaction rate among individuals with such a history, and such a history was obtained in 35 per cent of the penicillin reactors. Since some of the patients outside of the controlled series who were available to us for study following a penicillin reaction were obtained from a private practice in allergy, the overall group is weighted in favor of persons with a history of some previous manifestation of allergy.

The high incidence of reactors who had received previous penicillin is of interest (Table IV). In both the controlled series and the total group there was a large percentage of patients who had

TABLE V

previously received penicillin (40 and 45 per cent, respectively). In the controlled group the reaction rate among patients who had previously received penicillin was significantly higher than the rate among those to whom the penicillin was given for the first time (28 per cent versus 3 per cent).

Reactions in the controlled group were somewhat more frequent in males (12 reactions among 683 males) than in females (eight out of 600). The incidence of reactions in the white patients (eight in 389 patients) was greater than that for the Negroes (12 in 894 patients), but this is not statistically significant.

We had little success in demonstrating latent allergy by giving second courses routinely. Among 122 patients who received second courses of aqueous crystalline penicillin only one had a reaction, while 111 patients received a second course of crystalline penicillin in wax and oil and 28 a second course of procaine penicillin without exhibiting a reaction. Almost all of the intervals allowed between the first and second courses were under ten days, and the majority were three, four, or five days. The one reaction occurred on the third day of the second course, ten days following the first course.

Eight hundred and eighty-six patients were studied by daily observation for the occurrence of local irritative reactions, which were graded as mild, moderate and severe depending upon the degree of pain, tenderness, induration, edema, and redness present. It was found (Table V) that penicillin in oil and wax caused significantly more irritative reactions than aqueous crystalline penicillin (36 per cent compared with 12 per cent). Procaine penicillin in oil although it caused more mild local reactions than aqueous penicillin produced no moderate or severe reactions at all, and therefore in the doses used appeared to be the least irritating of the three preparations. In the case of penicillin in oil and wax and aqueous penicillin, the dose and duration of treatment appeared to be directly related to the incidence and severity of the local reactions.

DISCUSSION

The incidence of penicillin reactions has been reduced by the use of crystalline penicillin. Keefer and his colleagues (5) using crude penicil-

lin reported 69 reactions among 500 patients although it is uncertain how many of these were allergic in nature. Lyons (6) reported urticaria in 5.7 per cent of 209 patients receiving crude penicillin. Duemling (7) reported a 10 per cent reaction rate including Herxheimer reactions in 17,879 patients treated for 65 different conditions. The patients were treated over the years during which penicillin was being purified and thus penicillin of varying degrees of purity was used in these patients. Thomas and co-workers (8) reported 2.5 per cent of 10,000 syphilitics developed urticaria following therapy. Peck and co-workers (9) observed 32 reactions among 130 patients who received crystalline penicillin. The overall incidence of reactions in our series of 1.2 per cent for aqueous crystalline penicillin patients, 2.7 per cent for crystalline penicillin in oil and beeswax and 1.4 per cent for procaine penicillin in oil are compatible with most of these figures. Since some of our patients were discharged a few days after penicillin was discontinued and since we know that certain delayed penicillin reactions may occur after a longer interval than this even when the aqueous preparation is used, the reported rates may be somewhat low.

It is of interest that there are significantly more reactions when the penicillin is administered in oil and beeswax. Even though three of these reactions may have been caused by the vehicle (10), this does not account for all of the difference. The dose used is evidently not the key to the situation since the penicillin in oil and wax doses did not exceed the moderate range and when the reactions in this group are compared with those occurring in the aqueous penicillin patients who received comparable doses, the greater tendency of the oil and wax preparations to cause reactions is even more pronounced. Moreover, moderate doses of penicillin in oil and wax gave no higher reaction rates than the low doses (300,000 units per day). Two factors which may be of importance are that the penicillin is held in contact with the tissues in one site over a prolonged period of time, and in the same area as evidenced by the local irritation there are probably many damaged proteins which may conjugate with the penicillin and render it antigenic. Observation of a larger group of patients under treatment with procaine penicillin may indicate whether the prolonged

contact or the irritative component is more important. That more reactions of the delayed type occur after the use of penicillin in oil and wax than after the use of aqueous penicillin may indicate that the prolonged contact locally or systemically is important. Some of these reactions, however, are probably caused by a metabolic product of penicillin particularly since they do follow the use of aqueous penicillin. Inasmuch as the skin is an important organ for causing penicillin sensitization it is possible that the minute quantities of penicillin in oil and wax escaping into the cutaneous tissue are important. Small amounts of wax and oil will remain in the skin for a prolonged period when injected intracutaneously (4) and may hold penicillin there in contact with the tissue for some time.

The fact that the employment of very high doses of aqueous penicillin results in a high reaction rate may depend on the fact that these large amounts produce considerable local irritation, even though for only a relatively brief period, with the result that more proteins are available to conjugate with the large amount of penicillin present at the site. On the other hand the concentration of penicillin or a metabolic product of it in the distant organs may be more important. In this connection the fact that when high doses of penicillin are given the reaction rate approximates that obtained with a sulfonamide indicates that penicillin is rather allergenic in large doses and that the difference between it and the sulfonamides may be mainly a question of dosage.

Our data indicate that an underlying allergic diathesis may be important in the development of penicillin allergy. We have examined the histories of 138 patients reported in the literature. Among the cases in which a history of allergy is mentioned, the history was positive in 18 per cent.

Among the 138 histories examined, 63 patients had previously received penicillin therapy, locally or systemically, at least once and 16 patients had received none. No data on previous penicillin administration were recorded for the 59 remaining patients. If the latter patients are omitted from the calculation, about 80 per cent of the reactors had previous contact with penicillin. Our figures are in agreement with a high incidence of previous exposure.

In this connection our failure to demonstrate "latent" allergy by administering a second course of penicillin is of interest. It is possible that the interval allowed in many of the patients was too short, since we have observed delayed reactions after the discontinuance of penicillin with incubation periods longer than the time which we allowed between courses in most patients. Furthermore, the intervals in the patients who reacted to penicillin treatment were much longer both in our cases and in those reported, usually a matter of months rather than a few days.

Peck and co-workers (9) have reported that the incidence of reactions is much higher among males than among females. Although the rate was somewhat higher among our male patients than among our female patients, the difference was not statistically significant. The reaction rate in Negroes may be lower than that for white patients. This problem deserves further study.

The fact that the incidence of allergic reactions and local irritative reactions seem to parallel one another may indicate a cause and effect relationship as discussed above. This is not necessarily so, however, since several mechanisms are available to explain the production of each phenomenon. Certainly some patients with severe local reactions do not have allergic reactions whereas others with no demonstrable local reaction may have severe allergies so that even if the two phenomena are related other determinants may be operative.

SUMMARY

1. The incidence of allergic reactions was studied in 1303 patients. Among 598 patients receiving aqueous crystalline penicillin the rate was 1.2 per cent, among 557 patients receiving crystalline penicillin in oil and beeswax it was 2.7 per cent, and among 148 patients receiving procaine penicillin in oil it was 1.4 per cent. In patients receiving very large doses of the aqueous preparation the reaction rate was high (7.8 per cent). Reactions were more frequent when a product was administered for a longer period of time.

2. Reactions were more frequent among patients who gave a history of previous allergy or who had previous known contact with penicillin. The effect of sex and race on the incidence of reactions was not significant in this group of patients.

3. Local irritative reactions were more frequent and more severe with penicillin in oil and beeswax than with aqueous crystalline penicillin and procaine penicillin in oil. Higher doses and/or more prolonged therapy were likely to be accompanied by a higher incidence of irritative reactions.

THE RECOVERY OF BACTERIA FROM THE TOXIC EFFECTS OF PENICILLIN¹

By HARRY EAGLE

(From the Section on Experimental Therapeutics, National Institutes of Health, U. S. Public Health Service, Bethesda 14, Maryland)

There is considerable evidence that the therapeutic action of penicillin is determined primarily by the total length of time for which it remains at concentrations effective against the particular organism. It is, however, equally clear that the exposure to penicillin need not be continuous. Injections of aqueous penicillin may be given so infrequently that for an appreciable period of time the serum concentrations of the drug are below the limits effective against the particular organism, and yet such widely-spaced injections may be fully effective therapeutically. This raises the question as to why the bacteria fail to remultiply during the time that the serum concentrations are less than that necessary to kill the organisms *in vitro*. Several of the possible explanations are apparently not valid. We have not found the bacteria we have studied to be appreciably more sensitive to penicillin *in vivo* than they are *in vitro*. The concentrations necessary to effect cure are of the same order of magnitude as those required to kill the bacteria in the test tube. Similarly, we have not found that penicillin, after its intramuscular injection in aqueous solution, persists at effective levels in the tissues for a significantly longer period than in the blood.

This paper will describe some experimental data which may throw some light on this problem. The clue was the observation by Parker and Marsh (1) that after staphylococci had been exposed to penicillin, they did not immediately remultiply on the removal of the drug. Instead, there followed a period of recovery during which they remained essentially constant in number, and during which they were presumably recovering from the toxic effects of the drug. We have found this phenomenon to be observed with every bacterial species so far studied, whether with group A, group B or

group C β -hemolytic streptococci, α -hemolytic streptococci, type I or type III pneumococci, *Staphylococcus aureus*, *Staphylococcus albus*, or *Streptococcus fecalis*. After the bacteria have been exposed to penicillin, on the removal of the drug there follows a variable recovery period during which their numbers remain constant for a period of two, four, six, or even eight to 10 hours. Only after this period of recovery do the organisms begin to multiply at their normal rate (Figure 1). In some instances the toxic effect on the bacteria was manifested by a reduced rate of multiplication on the removal of penicillin, rather than an absolute bacteriostasis (Figure 2).

The rate at which this toxic effect is initiated, and the duration of the following recovery period, vary with individual bacterial species, and are affected also by two additional factors. One is the concentration of the drug to which the bacteria had been exposed (Figure 3). The toxic effect is initiated only by concentrations eventually bactericidal to the organism. The rate at which the toxic effect develops varies with the concentration of penicillin, and reaches a maximum at the concentration most rapidly bactericidal for the particular organism. Beyond that maximum, even a 10,000-fold increase in the concentration of penicillin does not further accelerate the rate at which the toxic effect is initiated.

The duration of the recovery period is affected also by the time for which the bacteria had been exposed to penicillin. With some strains (Figure 4) the toxic effect reaches its maximum within one to two hours, and even 24-hour exposure to penicillin does not significantly prolong the duration of the following recovery period. With other strains, however, the duration of the recovery period increases directly and continuously with the duration of the preceding exposure to penicillin (Figure 5).

It is apparent that a recovery period during which the organisms remain static in number provides a valuable margin of safety in the thera-

FIG. 1

peutic use of the drug, a period during which the organisms will not multiply even in the absence of penicillin. The therapeutic importance of this phenomenon, however, goes beyond the mere failure of the bacteria to multiply. We have found

that during this recovery period, bacteria previously exposed to penicillin are extraordinarily susceptible to the defense mechanisms of the body. Even highly virulent organisms against which the body ordinarily has so little defense that one or

FIG. 2

FIG. 3

two bacteria suffice to initiate a fatal infection become relatively avirulent after exposure to penicillin. In order to initiate a fatal infection, one must inject, not one, but 100, 1,000, or in several ex-

periments even 5,000 of these recovering but viable bacteria. As the bacteria recover from the toxic effects of penicillin, their virulence slowly returns, reaching its normal level at the time

FIG. 4

FIG. 5

FIG. 6

that the bacteria resume multiplication in the test tube (Figure 6). This decreased virulence of bacteria which have been acted on by penicillin can only mean that the organisms have become susceptible to the defense mechanisms of the host. One must inoculate as many as 100 or 1,000 bacteria in order to have at least one organism surviving by the time the bacteria have recovered sufficiently to resume multiplication and regain their normal virulence.

The therapeutic implications are two-fold. In the first place, bacteria should be, and are, killed by penicillin even more rapidly *in vivo* than they are *in vitro*. The bactericidal action in the infected animal is the sum of the direct effect of penicillin itself, plus the bactericidal action of the host mechanisms on organisms which are being acted on by the drug and thereby rendered susceptible. This has been found to be the case in a number of acute experimental infections of rabbits and mice. The relative quantitative importance of these two mechanisms is under present study. In the second place, the therapeutic action of penicillin persists well beyond the time for

which the drug remains at effective levels. For a varying period of time after penicillin has fallen below bactericidal concentrations, the damaged but viable bacteria continue to die under the impact of the host defense mechanisms. There is reason to believe that the number of bacteria killed during this penicillin-free period is usually less than those killed by the drug and the host during the period of penicillin action. The recovery period is nevertheless of major importance in that it provides a necessary and desirable margin of safety in the therapeutic use of penicillin. Even though the total length of time for which penicillin remains at effective levels may be the factor primarily determining its therapeutic efficacy, those levels need not be continuously maintained.

Studies are in progress to determine whether humoral or cellular host mechanisms are concerned in the death of bacteria which have been damaged by penicillin.

AMPEROMETRIC MICRO-TITRATION OF STREPTOMYCIN AND DIHYDROSTREPTOMYCIN¹

By JOHN B. CONN AND SARA L. NORMAN

(From the Research Laboratories of Merck & Co., Inc., Rahway, New Jersey)

With the introduction of dihydrostreptomycin into general use as an antibiotic, the development of a chemical assay procedure becomes desirable. Whereas adequate chemical methods exist for streptomycin, based on the characteristic maltol reaction (1, 2), dihydrostreptomycin does not respond similarly, and other techniques must be sought.

One property which is shared by both streptomycin and dihydrostreptomycin is the formation, under certain conditions, of sparingly soluble to insoluble salts with various anionic dyes, some of which are crystalline (3, 4). Since these dyes are polarographically reducible, it seemed possible that the precipitation reaction might be utilized in an amperometric titration procedure, which would have the advantage of being independent of other assay methods. When appropriate investigation was launched, it soon became apparent that no simple reaction was being dealt with. While a wide variety of acid azo dyes were found to give precipitates with dihydrostreptomycin salts in aqueous solution, the precipitates tended to be peptized by inorganic salts in concentration above a critical level or by excess dye, and further, would not separate at all unless the pH of the medium were held to a very narrow range. Inasmuch as polarographic methods require the presence of a supporting buffer electrolyte of concentration many times that of the component being measured, it was evident that dyes fulfilling the requirements would be rare.

Altogether, some seventy-odd dyes have been tested during the course of this work, of which 60 were commercial products, the remainder synthesized for the purpose. None of the commercial samples could be made to function in the desired manner; of the synthetics, those which showed promise were derived from diazotized 4-

aminobiphenyl and diazotized pararosanine, coupled with 1-naphthol-4-sulfonic acid.

The first of these, having the structure

would precipitate dihydrostreptomycin in 0.1N borate buffers of pH 7.5-8.5, but it was at once apparent that the composition of the precipitate was not the expected BA_3 , but contained much less dye. Moreover, a slow but steady drift toward zero occurred in the diffusion current after each addition of dye, once the equivalence point had been passed. Titrations carried out rapidly gave sharp apparent equivalence points, but the results were too erratic to be of value. After fruitless attempts to surmount the difficulty, which was caused by ion exchange between the precipitate and excess dye in solution, the use of this dye was abandoned.

A priori, the solution to the problem of variable precipitate composition would be to select a dye which could give a dihydrostreptomycin salt of but one type; namely, one having three acidic functions. The representative most easily prepared by unequivocal method has the structure

Trisodium tris-(naphtholazophenyl) carbinol trisulfonate

produced by diazotization of pararosanine and coupling with 1-naphthol-4-sulfonic acid. The red dye is soluble in water up to 0.05M (5%) and precipitates dihydrostreptomycin in 0.01M triethanolamine citrate buffer, pH 2.8, without any troublesome drift effects. (The use of triethanolamine citrate as supporting electrolyte was dictated by the peptizing action of the common inorganic cations.) The composition of the dihy-

drostreptomycin dye precipitate is not exactly stoichiometric, but is reproducible under the conditions of titration.

METHOD

Preparation of materials

It is essential that pure intermediates be used in the preparation of the dye; otherwise mixtures of variable behavior result. Neither commercial fuchsine, which consists of a mixture of pararosaniline and its methyl and dimethyl homologues, nor technical grades of 1-naphthol-4-sulfonic acid can be used. Eastman Kodak best grade pararosaniline base is suitable, while a pure grade of 1-naphthol-4-sulfonic acid is easily prepared from Eastman Kodak best grade 1-naphthylamine-4-sulfonic acid via the Bucherer reaction (5).

Suspend 15.3 g. (0.05 mole) finely pulverized pararosaniline base in 500 ml. water, cool to 5°, add 27 ml. conc. hydrochloric acid, and diazotize by dropwise addition of 10.4 g. (0.15 mole) sodium nitrite in 100 ml. water over the period of one hour, with continuous stirring. At the end of the process, the solution should be orange and no particles of unreacted pararosaniline chloride should be present. The diazonium salt solution is poured with stirring into a solution of 37 g. (slight excess over 0.15 mole) pure 1-naphthol-4-sulfonic acid in 500 ml. water containing 14 g. sodium hydroxide, chilled to 5°. The dark red solution is stirred for one hour at 5°, filtered, and treated with 10 g. ammonium chloride (to lower the pH), after which it is allowed to stand at room temperature overnight. The dye solution is salted out with sodium chloride and centrifuged; the precipitate is suspended in sufficient water to render the mixture fluid, poured into a cellophane sac, and dialyzed against running water for 36–48 hours to remove diffusible electrolytes (it has not been found possible to date to crystallize the dye). The dialyzed solution is concentrated to dryness on the steam bath, and the vitreous green residue further dried at 100°. Yield, 50.4 g. (93%). M.W., 1079.

For preparation of the titrating solution, 1.08 g. (0.001 mole) is dissolved in 100 ml. water by warming; the solution is allowed to stand for two days, and then filtered through a layer of Celite to remove any insoluble particles.

Supporting buffer: Dissolve 29.8 g. (0.2 mole) commercial triethanolamine and 21.0 g. (0.1 mole) citric acid in 1 liter water and mix 400 ml. of this solution with 600 ml. 0.1N HCl. This stock solution is diluted 1:10 with distilled water for use; the pH should be 2.8.

Procedure

A Leeds and Northrup Electro-chemograph was used in conjunction with a Lingane-Laitinen cell (6), the equipment being housed in a room thermostated at 25°. The burette was a 1 ml. mercury-expulsion type of the Gilment design.

The potentiometer is set at -0.8 v. vs. S.C.E., and recorder range at 10 micro-amperes. The cell is charged

with 5–10 ml. buffer, and a sample of dihydrostreptomycin salt equivalent to 1–3 mg. base is introduced either in a small platinum boat or as a measured amount of solution. After nitrogen is passed through the solution for five minutes, the gas flow is switched to overpass and a chart tracing obtained after establishment of equilibrium, the chart being allowed to run until a straight line is drawn, stopping for convenience on a chart division. Nitrogen is once more passed through the solution, and 0.05 ml. of dye is introduced, after which a second chart tracing is obtained. This cycle of operations is repeated until the equivalence point has been passed and four or five current steps of about equal magnitude are obtained. The chart is read off, the current values corrected for volume change and the results plotted.

Standard preparations of streptomycin and dihydrostreptomycin salts are employed for calibration purposes. If streptomycin hydrochloride-calcium chloride double salt is used, the calcium chloride is best removed, so as to avoid any disturbing effect due to its presence. This is easily accomplished by stirring the solution of the sample with silver carbonate until the pH rises above 8; the solid is removed by centrifugation, washed, and the combined solution phases brought to pH 5 with dilute acid.

RESULTS AND DISCUSSION

Table I lists data which have been collected on the titration of various dihydrostreptomycin salts.

In view of the usual difficulties of solvation and hygroscopicity which are encountered in dealing with these salts, the agreement is considered good, particularly since the amperometric titration depends on a property of the ion as a whole rather than any functional part.

TABLE I
Titration of dihydrostreptomycin salts

Salt	Amperometric assay	Other assays
Sulfate	734 743	
Chloride	808 817	
Sulfate	760 765	
Sulfate	782 790	765 (Base titration)
Sulfate	737 749	763 (Iodimetric)
Streptomycin Hydrochloride-Calcium Chloride	748 733	740 (Maltol)

TABLE II
*Stability of dihydrostreptomycin
in normal sulfuric acid*

Time (hours)	Temperature	Decomposition (%)
1	100°	100
23	25°	25
95	25°	77

In practice it is found that separate standardizations are required for streptomycin and dihydrostreptomycin salts, since the molecular compositions of the salts are neither exactly stoichiometric nor identical. This effect is not unexpected, in view of the colloidal nature of the anion.

Since, as has been previously pointed out, inorganic salts exert a strongly peptizing action on streptomycin and dihydrostreptomycin tris-(naphtholazophenyl) carbinol trisulfonate, applications of the amperometric assay are limited to those in which such salts are either absent or removable. For example, in case it is desired to use the method for a study of the stability of dihydrostreptomycin in aqueous solution at different pH's and temperatures, the employment of sulfuric acid and barium hydroxide as acid and base permits removal of extraneous ions. The data in Table II on the acid stability of dihydrostreptomycin were obtained in this manner.

SUMMARY

Streptomycin and dihydrostreptomycin form water-insoluble salts with various anionic dyes; this property may be utilized for a precipitometric titration assay, provided that the characteristic tendency of the precipitate to be peptized by excess of indifferent salts can be overcome. In addition,

unless the dye anion is trivalent, precipitates of variable composition are likely to be produced.

The dye formed by coupling diazotized parosaniline with 1-naphthol-4-sulfonic acid precipitates streptomycin and dihydrostreptomycin quantitatively in 0.02M triethanolamine citrate buffer, pH 2.8. The polarograph is used in an amperometric titration procedure; an amount of streptomycin or dihydrostreptomycin salt corresponding to 1-3 mg. of base dissolved in 5-10 ml. buffer is titrated with 0.01M solution of dye, using a 1 ml. micro-burette; the polarograph is set at -0.8 v. (vs. S.C.E.) and 10 micro-ampere range.

The titration is reproducible to better than $\pm 1\%$. Using pure streptomycin and dihydrostreptomycin salts as standard, the method gives results in good agreement with other assay procedures.

A NEW LINEAR DIFFUSION METHOD FOR THE MICROBIOLOGICAL ASSAY OF STREPTOMYCIN AND DIHYDROSTREPTOMYCIN¹

By J. M. McGUIRE, W. W. DAVIS, T. V. PARKE, AND W. A. DAILY

(From the Lilly Research Laboratories, Indianapolis, Ind.)

A new antibiotic assay method has been developed which involves a radically different diffusion system from that employed in plate methods. In this new method diffusion occurs from a solution of the antibiotic in a test tube into a column of agar contained in a glass capillary.

This new method promises improved accuracy because the linear diffusion system has important advantages over the diffusion system presented in the plate methods. Secondly, this method provides greater efficiency in handling test equipment than is possible for other methods. Capillaries can be filled, read, and cleaned by semiautomatic procedures. Test tubes and other essential equipment are efficiently cleaned in a special steam cabinet. Finally, the method affords comparative economy in personnel and materials over other methods.

The method is inherently capable of extension to testing of other antibiotic or germicidal materials, but has been worked out in detail and applied only for the testing of streptomycin and dihydrostreptomycin. The obvious extension to testing of penicillin is being studied.

The test depends upon the formation of characteristic zones in the seeded agar column in the capillary. Figure 1 shows a section of a capillary in which such zones have formed.

A sharp initial boundary for diffusion of antibiotic from solution into the agar column is provided by the molded end of the agar column. A region of inhibition of growth occurs at this end of the agar column. The length of this region depends on concentration of antibiotic in the test solution. This region is bounded by a sharp dense zone of aerobic growth of the test organisms which allows the length of this region to be accurately measured. This sharp zone of aerobic growth results from the fact that oxygen diffuses unused

through the region of inhibition and becomes available to the first uninhibited organisms encountered. Since this growth uses all the oxygen available by diffusion inward, the growth of organisms beyond this zone is limited by the oxygen originally dissolved in the agar. Accordingly, growth in this region is very light. A pellicle of dense aerobic growth is always seen at the top surface of the agar column.

Figure 2 shows the manner in which the length of the inhibition region depends upon the concentration of dihydrostreptomycin in test solutions. Such a standard curve is prepared each day from known dilutions of a standard solution. The results on unknown solutions are referred to this curve for evaluation.

METHOD

A complete description of the required equipment and the details of the method is being published elsewhere. Only a brief description of the operations involved in the use of this method can be given here.

FIG. 1. SCHEMATIC DRAWING SHOWING THE REGIONS OF GROWTH IN THE AGAR COLUMN

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

FIG. 2. A TYPICAL CURVE SHOWING THE DEPENDENCE OF ZONE LENGTH ON CONCENTRATION OF ANTIBIOTIC

The capillaries employed are constructed of pyrex capillary tubing of approximately 1.5 mm. bore and approximately 7 mm. outside diameter. They are cut to approximately $3\frac{1}{2}$ inches. One end is ground flat while the other is only edge ground.

Clean dry capillaries are partially filled by placing them in an automatic filling device containing plain 4% melted agar seeded with spores of *Bacillus subtilis*. This device fills 800 capillaries simultaneously. After the capillaries are filled, the entire assembly is cooled to allow solidification of the agar. This operation provides a flat molded end on the agar column in each capillary.

After cooling, the filled capillaries are removed from the filling device and placed two each in test tubes containing roughly 2 ml. of test solution. The test solutions have been made up by diluting standard and unknown antibiotic solutions with nutrient broth. The concentrations of standard test solutions are from 0.5 to 2.0 units per ml., while the unknowns are diluted to bring them to approximately 1 unit per ml. The test tubes are capped and incubated in racks in a constant temperature water bath at 32° C. overnight. After incubation the contents of a group of test tubes (usually five) containing a single test solution are dumped on a draining device. The capillaries are rinsed with water and then dried on an absorbent surface.

The capillaries are then transferred in a group to a special carriage provided on a modified Fisher-Lilly Antibiotic Zone Reader. The modification of the reader permits the length of the zone of inhibition to be read reproducibly to plus or minus 0.01 mm.

After the reading, the capillaries are stacked in a wire basket and cleaned simultaneously in the steam cleaning cabinet. Test tubes and bottles used for dilutions are cleaned in a similar manner.

The filling device formerly employed allowed simultaneous filling of 400 capillaries. Three units of test equipment are now being constructed, each designed to fill and handle 800 capillaries per day. Each unit anticipates the performance of 57 six-tube tests or 114 three-tube tests in addition to a complete standard curve.

RESULTS AND CONCLUSIONS

Deviations of test results on a 1 unit per ml. solution have been studied employing the disc-plate method and the capillary-linear diffusion method. Fifty Petri dishes were employed in each plate-disc experiment and 50 test tubes in each capillary experiment. The standard deviations for six plate-disc experiments were from

7% to 10% for individual zones, and those for seven capillary experiments were from 3% to 8% for individual capillaries. A similar experiment was performed to study the deviations of the broth-turbidimetric assay method, employing 150 tubes. The standard deviation of this method was found to be 3%. These data indicate that

when the two diffusion assay methods are compared on the basis of equivalent numbers of plates and pairs of capillaries, the linear diffusion capillary method is somewhat superior to the plate method in precision. In comparison to the broth-turbidimetric assay method the capillary method is less precise but more convenient.

QUANTITATIVE DETERMINATION OF DIHYDROSTREPTOMYCIN BY PERIODATE OXIDATION¹

By EDWARD A. GARLOCK, JR., AND DONALD C. GROVE

(From the Federal Security Agency, Food and Drug Administration, Washington, D. C.)

Dihydrostreptomycin is produced commercially by the catalytic hydrogenation of streptomycin. The reaction involves the reduction of the aldehyde group in the streptose moiety of the streptomycin molecule to the corresponding primary carbinol group as evidenced by the failure of dihydrostreptomycin to react with carbonyl reagents or with alkali to produce maltol. As there are no chemical methods available for the direct determination of dihydrostreptomycin, it was desirable to investigate the development of such a method. A satisfactory procedure has been found and is based upon the measurement of formaldehyde liberated by the periodate oxidation of dihydrostreptomycin.

Periodate oxidation is a general method of cleaving the linkage between two adjacent hydroxyl bearing carbon atoms. If one of the hydroxyl groups is a primary carbinol, formaldehyde will be a reaction product (1). In the elucidation of the structure of streptomycin, it has been proven there is no primary carbinol group which will give rise to formaldehyde on treatment with periodate (2, 3). However, in the case of dihydrostreptomycin there is a primary carbinol adjacent to an hydroxyl, and formaldehyde is liberated by periodate oxidation. This has been observed experimentally by Lemieux, DeWalt and Wolfson (4). These workers showed that dihydrostreptomycin when oxidized with 1.5 mole of periodate yielded 0.5 mole of formaldehyde while streptomycin yielded no formaldehyde. Fried and Stavely (5) have also found that the action of periodic acid on streptomycin B and on dihydrostreptomycin B produces zero and one mole of formaldehyde, respectively.

Sodium metaperiodate was found to be the most suitable reagent for the oxidation of dihydrostreptomycin. Although the action of the salt

is not as rapid as the free periodic acid, there is less danger of hydrolysis with the salt because of the difference in the pH of the solutions. Chromotropic acid (1, 8 Dihydroxynaphthalene-3, 6-Disulfonic Acid) was selected as the best reagent to determine the liberated formaldehyde (6). Attempts to determine the formaldehyde with this reagent in the presence of the other oxidation products were not satisfactory. As a result, it became necessary to distill the formaldehyde from the reaction solution and then determine the formaldehyde in the distillate by means of the chromotropic acid reagent.

PROCEDURE

An aqueous solution of the dihydrostreptomycin salt is prepared to give an estimated 20,000 µg/ml. A 5-ml aliquot of this solution is transferred to a 50-ml glass stoppered flask and 10 ml of an aqueous 0.05M sodium metaperiodate solution added. The oxidation is allowed to proceed overnight at room temperature. After oxidation, a 3-ml aliquot is transferred by means of a pipette to the distilling bulb (Figure 1). An excess of sodium thiosulfate (approximately saturated solution) is added to destroy any remaining periodate. The formaldehyde is then distilled by steam while passing a small stream of air through the system to aid the distillation. Approximately 48 ml of distillate is collected in a 50-ml volumetric flask and made to volume with water. A 1-ml aliquot of the distillate is transferred to a 50-ml volumetric flask and 10 ml of concentrated sulfuric acid is slowly added. One ml of the chromotropic acid reagent (2.5 grams chromotropic acid plus 0.5 gram sodium bisulfite per 100 ml water) is added and the flask is heated in a boiling water bath for 15 minutes. The solution is cooled, distilled water is added with cooling and the solution finally made to 50 ml with distilled water at room temperature. A blank is prepared by adding 1 ml of water, 10 ml of concentrated sulfuric acid, 1 ml of chromotropic acid reagent, heating and making to volume as above. The per cent transmittance of the unknown solution is read in a 1-cm cell in a photoelectric colorimeter, using a 575-mµ filter and setting the instrument at 100 per cent transmittance for the blank solution.

A standard curve is prepared by oxidizing a standard solution of dihydrostreptomycin, distilling aliquots into separate 50-ml flasks and treating the distillates as indicated above with chromotropic acid. The per cent transmittances obtained on the standard solutions are plotted

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

TABLE I

*Comparison of chemical and bioassay of commercial samples of dihydrostreptomycin**

Mfgr.	Type salt	Grams of dihydrostreptomycin per vial	
		Chemical	Bioassay
A	Sulfate	1.10	1.11
	Sulfate	1.10	1.04
B	Hydrochloride	1.10	.99
	Hydrochloride	1.12	1.12
C	Sulfate	1.06	1.04
	Sulfate	.90	1.05
D	Sulfate	1.06	1.03
	Sulfate	1.05	1.08
E	Sulfate	1.23	1.06
	Sulfate	1.05	1.00

* All of the above samples were labeled to contain one gram of dihydrostreptomycin per vial.

as the ordinate on semi-log paper against the concentrations in micrograms of the dihydrostreptomycin standard as the abscissa. A straight line relationship is obtained. The per cent transmittance of the unknown is located on the curve and the corresponding concentration of dihydrostreptomycin read off the graph.

Table I shows the values obtained when ten commercial samples were analyzed by this procedure as compared to the turbidimetric bioassay method. The values indicate a good agreement between the two methods. The standard dihydrostreptomycin sulfate² used in this study was a relatively pure sample as determined by chemical and biological assay.

A series of streptomycin samples were analyzed for their dihydrostreptomycin content by this

² Supplied through the courtesy of Chas. Pfizer & Co., Inc.

FIG. 1. DISTILLATION BULB FOR DISTILLING FORMALDEHYDE WITH STEAM

procedure. Two samples (both from the same manufacturer) showed 10 and 13 per cent dihydrostreptomycin while the others showed less than 6 per cent. It is possible that impurities capable of reacting with periodate to give formaldehyde are responsible for some of the apparent dihydrostreptomycin content of these commercial streptomycin samples. The FDA streptomycin sulfate working standard showed less than 3 per cent dihydrostreptomycin by the above method. A relatively pure sample of streptomycin B³ also showed less than 3 per cent dihydrostreptomycin as determined by this procedure. The data obtained during this study indicate the proposed chemical method is reliable for the analysis of relatively pure dihydrostreptomycin samples.

SUMMARY

Dihydrostreptomycin may be quantitatively determined by the colorimetric measurement of the formaldehyde liberated after oxidation with periodate.

INVESTIGATIONS ON THE STREPTOMYCINS¹

By GEOFFREY RAKE, FELIX PANSY, WILLIAM P. JAMBOR,
AND RICHARD DONOVICK

(From the Squibb Institute for Medical Research, New Brunswick, N. J.)

Studies *in vitro* and *in vivo* with pure preparations of streptomycin, dihydrostreptomycin, mannosidostreptomycin and dihydromannosidostreptomycin have been continued. Unfortunately, up to the present only small amounts of the two latter antibiotics have been available in the pure form and for this reason *in vivo* studies have been carried out only with the two former.

Careful studies of the *in vitro* activity of these four streptomycins on nine species and 16 strains have been reported elsewhere (1). In general a pattern of activity was established which showed approximately equal activity of streptomycin and dihydrostreptomycin in terms of minimal inhibiting concentrations (M.I.C.) of antibiotic. Mannosidostreptomycin and dihydromannosidostreptomycin also showed M.I.C.'s equal to each other but significantly higher than streptomycin and dihydrostreptomycin, *i.e.* the mannosido-compounds were less active. The chief exceptions to this pattern were with *S. typhosa* and *S. schottmülleri* where dihydrostreptomycin was much less active than streptomycin but the mannosido-compounds showed activity similar to that of streptomycin.

Further *in vitro* studies have confirmed this general pattern of activity. In Table I are shown the data for nine species of which two have not been reported previously—*H. influenzae* and *D. granulomatis*. They follow the usual pattern. Of note is the fact that in both cases the dihydro compounds are slightly but significantly more active, and that *D. granulomatis* is by far the most sensitive strain we have tested so far.

In Table II are shown the *in vitro* results with 12 strains of seven species of *Salmonellae* and *Shigellae*. Although the two species of *Shigella* fit in with the pattern discussed above and shown by the strains in Table I, the *Salmonellae* are

atypical as already indicated in the previous publication (1). Moreover, there are three distinct groupings with the *Salmonellae*. All strains show a higher resistance to dihydrostreptomycin than to streptomycin, this being least marked with *S. enteritidis* where the activity of the dihydro compound almost equals that of streptomycin while it is only one-third to one-fourth as active as the latter compound for the other species. The three distinct groupings appear when the activity of the mannosidostreptomycins is considered. With *S. enteritidis* the pattern resembles that of *Shigella* and the other microorganisms. With all strains of *S. typhosa* and *S. schottmülleri* the mannosidostreptomycins have an activity in terms of M.I.C. approximately equal to that of streptomycin while with *S. pullorum* and *S. gallinarum* the mannosidostreptomycins are more than twice as active. This activity of the mannosidostreptomycins against the *Salmonellae* is of particular interest in consideration of the mode of action of the different streptomycins. Although in the case of most organisms it might be hypothesized that the mannosidostreptomycins were only active after conversion to streptomycin, and that their lesser activity was due to incomplete conversion by the organisms involved, such cannot be the case with their activity on *S. pullorum* and *S. gallinarum* and the whole hypothesis must thus be put in question.

Unfortunately, at the present time insufficient amounts of the pure mannosidostreptomycins are available for *in vivo* tests. At this time further *in vivo* experiments with streptomycin and dihydrostreptomycin will be described and the results of different dosage schedules with these two compounds will be evaluated.

In Table III are seen the composite results of several tests comparing the activity of streptomycin and dihydrostreptomycin against *Rickettsia microti*—the vole rickettsia of Baker, in the egg. It will be noted that dihydrostreptomycin is twice as active as streptomycin itself. This finding is the reverse of those of Smadel, Jackson and Gauld (2) with other species. They found di-

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

hydrostreptomycin less than half as active as streptomycin in the egg against *R. rickettsii* and *R. akari*.

In seeking to obtain definitive data on the usefulness of different dose schedules both acute and chronic infections have been employed. In Table IV are shown the results with one of the acute infections used, namely, that with *S. schottmülleri*. It will be noted that in all cases a single daily dose schedule is better (*i.e.* the CD_{50} is less) than is a three dose schedule. This is more marked where

a small bacterial inoculum is used but even with larger inocula the results are significant. In this table one should draw attention to a phenomenon mentioned before (1), namely, that dihydrostreptomycin is more active *in vivo* (better than half as active as streptomycin) than might be expected from its *in vitro* activity (see Table II).

With more chronic infections there is no actual advantage to the single dose schedule. Instead, one, two, or three dose schedules all give the same response. This is shown in Tables V and

schedule over another whether the total daily dose is 10,000 or 50,000 units per kg or whether treatment is maintained for seven, 14 or 21 days.

In general, it can be said then that no benefit can be expected in setting up any standardized test for the streptomycins with a dosage schedule using greater frequency than one dose a day. One would presume that the same would hold for the mannosidostreptomycins when they become available.

SUMMARY

In vitro studies continue to reveal unique behavior on the part of the various strains of *Salmonellae* in their response to the four streptomycins. Where with most other species the activity of dihydrostreptomycin equals that of streptomycin, in this genus all strains tested are less sensitive to the former than to the latter, all comparisons being made on a weight basis. On the other hand, for most genera studied the mannosidostreptomycins are less active than is streptomycin. In contrast to this for the *Salmonellae*, the mannosido compounds are often as active as streptomycin, and for two species are even more active than the latter. The characteristics of dihydrostreptomycin mentioned above do not hold for dihydromannosidostreptomycin which approximately equals mannosidostreptomycin in activity for every species tested thus far *in vitro*.

In vivo studies in acute as well as in chronic experimental infections show that streptomycin or dihydrostreptomycin given in a single dose daily gives results as good as, or better than, those obtained by giving two to three divided doses daily. Against *S. schottmülleri* dihydrostreptomycin is more active than might be expected from the *in vitro* findings. In embryonated eggs infected with *Rickettsia microti* dihydrostreptomycin is somewhat more active than streptomycin.

THE EFFECT OF STREPTOMYCIN DERIVATIVES ON STREPTOMYCIN-DEPENDENT AND -RESISTANT STRAINS OF BACTERIA¹

By WALTER A. WINSTEN

(From the Food Research Laboratories, Inc., Long Island City, New York)

Several authors (1, 2) have recently demonstrated the value of streptomycin-dependent strains of bacteria for the identification of streptomycin-producing organisms. The occurrence of streptomycin-dependent mutants of various bacteria was first demonstrated by Miller and Bohnhoff (3, 4). The streptomycin-dependent mutants were found in cultures which also contained streptomycin-resistant strains of the usual type.

In the case of the streptomycin-dependent strains, these organisms, according to Iverson and Waksman, apparently utilize streptomycin as a true growth factor. The authors stated that streptomycin is not used as a substrate or a nutrient since no destruction of streptomycin occurred in media in which the streptomycin-dependent strains were grown.

Accepting the suggestion that streptomycin represents a true growth factor for the mutant forms discussed above, it was of interest to determine whether any synthetic streptomycin derivatives could act either as anti-metabolites vis-à-vis the "growth factor" streptomycin or possibly as substitute growth factors for a streptomycin-dependent organism. It was also thought of interest to extend the study to include the effects of various streptomycin derivatives on streptomycin-resistant bacteria, as well.

Various streptomycin derivatives were therefore tested for antistreptomycin or streptomycin-like activity. The derivatives examined included dihydrostreptomycin (5) and certain N-substituted straight chain alkyl streptomycylamines first described by Winsten (6).

In testing different preparations of the streptomycylamine derivatives, it was necessary to insure that each derivative was tested for its effects free of any residual unchanged streptomycin or dihydrostreptomycin formed during the course of the

synthesis of the streptomycylamine derivatives by catalytic hydrogenation of the corresponding Schiff bases. This could be most conveniently done by use of the paper chromatographic method of Winsten and Eigen (7).

METHODS

In carrying out the present study a solution of each preparation of a derivative (or derivatives) was first subjected to paper chromatographic separation. The resulting paper chromatograms were then laid on agar seeded with *E. coli* Strain E 158, a streptomycin-dependent strain obtained through the courtesy of Dr. R. J. Vanderlinde.

A desired amount of streptomycin was included in the Difco nutrient agar, in order to insure sufficient background growth of *E. coli* E 158 where this was desired. After incubation the substances being tested either caused enhanced zones of growth or zones of inhibition, seen along the loci of the strip chromatograms. The zones of growth were seen against the lighter background growth caused by the streptomycin in the medium. The zones of inhibition were seen as on usual plates against the background bacterial growth. Indeed it sometimes occurred that a locus of a chromatogram exhibited both a zone of growth and a zone of inhibition. This situation occurred whenever a preparation of a derivative which was an inhibitor also contained unchanged streptomycin or dihydrostreptomycin which caused zones of growth. A schematic drawing of such a chromatogram is shown in Figure 1 for the case of an N-n-hexylstreptomycylamine preparation.

RESULTS

The results of a series of experiments in which dihydrostreptomycin, streptomycin and different preparations of the N-substituted straight chain alkylstreptomycylamine derivatives were first subjected to paper chromatography and then tested against *E. coli* E 158 are given in Table I.

From the table it is apparent that streptomycin and dihydrostreptomycin cause zones of growth of *E. coli* E 158, when the agar contains 10 γ /ml of streptomycin. At a level of 100 γ /ml of streptomycin the background growth was quite heavy, thus obscuring zones of growth caused by these two substances.

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

Rake (8) has also reported that organisms which require streptomycin for growth can also use dihydrostreptomycin for the same purpose.

It is also evident from Table I that in the presence of 10 γ of streptomycin per ml of agar, N-n-

* 10-microliter samples of 1–6% solutions of the various preparations were chromatographed on Whatman No. 1 or No. 4 paper for 18 hours using butanol-2% piperidine-2% p-toluenesulfonic acid as the developing solvent.

† The N-n-hexyl derivative in one experiment caused a hazy zone of inhibition. In a second experiment it caused no zone.

propylstreptomycylamine did not cause a zone of growth or of inhibition. The N-n-butyl derivative and higher homologues caused zones of inhibition. In the presence of 100 γ of streptomycin per ml of agar, the N-n-propyl and N-n-butyl derivatives caused no zones of inhibition whereas the higher homologues did so. The N-n-hexyl derivative appears to be a borderline case; in one experiment a zone of inhibition hazy in character was observed whereas in a second experiment no zone of inhibition was observed.

From these findings for the streptomycin-dependent *E. coli* E 158, there would appear to be an interesting metabolite-antimetabolite relationship between streptomycin and various N-substituted streptomycylamine derivatives which is some function of the length of the substituent side chain.

The above studies have been extended to a streptomycin-dependent strain of *S. aureus*. Starting with *S. aureus* SM, there was isolated an organism which grew readily in broth containing 1000 γ /ml of streptomycin. The culture was found to contain organisms which required streptomycin for growth. It was possible by subculture in streptomycin-free media to obtain organisms which grew in the absence of and were resistant to streptomycin.

N-n-hexylstreptomycylamine	G
N-n-octylstreptomycylamine	I
N-n-decylstreptomycylamine	I
N-n-dodecylstreptomycylamine	I

* 10-microliter samples of 1–6% solutions of the various preparations were chromatographed on Whatman No. 1 or No. 4 paper for 18 hours at room temperature using butanol-2% piperidine-2% p-toluenesulfonic acid as the developing solvent.

It is therefore likely that the culture containing the streptomycin-dependent organisms also contained a resistant strain as well. Using this mixed culture seeded into agar containing 30 γ /ml of streptomycin to promote the background growth of the dependent strain, the results recorded in Table II were obtained in a manner similar to that described earlier for *E. coli* E 158. Inspection of the data shows that streptomycin, dihydrostreptomycin and the shorter chain streptomycylamine derivatives up to hexyl caused zones of growth. The longer chain length derivatives caused zones of inhibition.

It is interesting to compare these results for a streptomycin-dependent strain of *S. aureus* with those obtained for *E. coli* E 158. It will be recalled that in the case of *E. coli* the N-n-propylstreptomycylamine derivative caused neither a zone of growth or of inhibition. On the other hand the streptomycin-dependent strain of *S. aureus* can utilize not only the N-n-propyl derivative for growth but the N-n-butyl and N-n-hexyl derivatives as well, both of which two latter derivatives inhibit *E. coli* E 158.

It would therefore appear that there are differences of major importance between different streptomycin-dependent organisms with regard to their response to streptomycylamine derivatives.

In the light of the above findings it was of interest to extend these studies to a streptomycin-resistant organism. It is well known that an organism resistant to streptomycin is also resistant to dihydrostreptomycin. It was anticipated that

some streptomycin-resistant bacteria might be sensitive to various members of the N-substituted streptomycylamine family of antibiotics. Such appears to be the case for at least one highly streptomycin-resistant strain of *S. aureus*.

Preparations of N-n-propyl-, N-n-butyl- and N-n-hexylstreptomycylamine were first tested, using the paper chromatographic technique, against the parent strain *S. aureus* H from which a highly streptomycin-resistant strain was derived. The results of this experiment appear in Figure 2.

Inspection of Figure 2 reveals that the N-n-propyl preparation contained the faster moving derivative itself, some dihydrostreptomycin, and two slow moving antibiotics of unknown structure which formed a curious doublet zone of inhibition. The zones of inhibition appear somewhat smeared; this was probably due to the use of Whatman No. 4 paper, a chromatographically very fast paper.

Figure 2 also reveals that the N-n-butylstreptomycylamine preparation, chromatographed on the slower Whatman No. 1 paper, exhibited a zone due to the fast moving N-n-butyl derivative itself as well as two small zones of inhibition due to dihydrostreptomycin (the slowest antibiotic in the preparation) and streptomycin.

Chromatographic analyses of the N-n-hexylstreptomycylamine preparation used in this experiment reveal in Figure 2 that the particular preparation used contained only a trace of the fast moving N-n-hexyl derivative itself. The main zone of inhibition observed in Figure 2 for this preparation is due to streptomycin itself. The N-n-hexyl preparation therefore merely serves to provide streptomycin as a control substance in the plate chromatographic test of Figure 2.

In Figure 3 are shown the results of chromatographing identical amounts of the N-n-propyl, N-n-butyl, N-n-hexylstreptomycylamine preparations studied in Figure 2, using a highly streptomycin-resistant strain of *S. aureus* derived from *S. aureus* H as the test organism. From the figure it is evident that only the N-n-propyl- and N-n-butylstreptomycylamine derivatives caused readily visible zones of inhibition. If one examines the chromatogram of the N-n-hexyl preparation, the large residual streptomycin zone present in Figure 2 for the parent *S. aureus* H is now completely absent for the highly resistant daughter strain of

S. aureus derived from H. A trace zone due to the N-hexyl derivative itself can be seen on careful inspection of Figure 3 at about the same point as in Figure 2. In a separate experiment a second preparation of N-n-hexylstreptomycylamine containing a larger amount of the derivative as is evident in Figure 1 caused a larger zone of inhibition at a comparable point on the chromatogram. The zone was present when either *S. aureus* H or its streptomycin-resistant offspring was used as the test organism.

In still other experiments the N-n-octyl- and the N-n-decylstreptomycylamine derivatives caused zones of inhibition when using the resistant *S. aureus* as the test organism. These zones however were turbid or hazy, suggesting merely a retarded growth of the organism rather than complete inhibition.

The findings in Figure 3, wherein a highly streptomycin-resistant strain of *S. aureus* was inhibited by the N-n-propyl and the N-n-butyl derivatives, were confirmed in serial dilution tube assays. Whereas the resistant strain derived from *S. aureus* H was not inhibited by as much as 10,000 γ per ml of streptomycin, it was completely inhibited in a 24 hour test by 5 γ per ml of the N-n-propyl derivative or 4 γ per ml of the N-n-butyl derivative. 25 γ per ml of the N-n-decyl derivative were needed for inhibition while the N-n-octyl derivative failed to inhibit as 100 γ per ml (the highest amount tried). *S. aureus* H itself was inhibited by 1 γ per ml of streptomycin, 16 γ per ml (or less) of the N-n-propyl derivative and 63 γ per ml of the N-n-butyl derivative.

DISCUSSION

The above findings suggest that it may be possible to obtain N-substituted streptomycylamine derivatives which are active against streptomycin-resistant strains of bacteria. The results indicate however that a derivative active against one streptomycin-resistant organism may not be active against another. This is based on the findings reported earlier in this paper where the N-n-butyl derivative could be used for growth by one streptomycin-dependent organism (an *S. aureus*), but caused inhibition of another streptomycin-depend-

ent strain (*E. coli* E 158) by antagonizing the growth promoting influence of streptomycin.

The results reported in this paper suggest that it may be possible to obtain a particular streptomycin derivative active against a particular streptomycin-resistant strain of bacteria. Further studies along this line will be reported at a later date.

SUMMARY

1. A streptomycin-dependent strain of *E. coli* was inhibited by various members of an homologous series of N-substituted alkyl streptomycylamines, in the presence of streptomycin.
2. A streptomycin-dependent strain of *S. aureus* was found capable of using N-n-propyl-, N-n-butyl-, and N-n-hexylstreptomycylamine for growth, replacing the need for streptomycin. Higher homologues inhibited the growth of the organism in the presence of streptomycin.
3. A streptomycin-resistant strain of *S. aureus* was inhibited markedly by N-n-propylstreptomycylamine, N-n-butylstreptomycylamine, and N-n-decylstreptomycylamine.

THE DEVELOPMENT OF RESISTANCE OF *SALMONELLA TYPHOSA* TO THE FATTY ACID SALTS OF STREPTOMYCIN AND DIHYDROSTREPTOMYCIN¹

By HENRY WELCH, HENRY FISCHBACH, C. W. PRICE, AND C. H. SHAFFER

(From the Federal Security Agency, Food and Drug Administration, Washington, D. C.)

Since the discovery of streptomycin by Waksman (1) there have been two major problems involved in its clinical use. Streptomycin was shown early to be inherently toxic, causing eighth-nerve damage in relatively low doses, particularly when given over a long period of time. In addition, all organisms sensitive to streptomycin have been shown to develop resistance to it rapidly, and the resistance is not only demonstrable *in vitro* but *in vivo* as well. The development of dihydrostreptomycin has partially answered the problem concerning streptomycin toxicity; however, organisms become resistant to dihydrostreptomycin with the same facility and to a similar degree. In the present study, an attempt has been made to develop salts of streptomycin and dihydrostreptomycin to which organisms either do not develop a resistance or develop resistance less readily than they do to the salts now available.

It has been known for some time that fatty acids or derivatives of fatty acids may influence markedly the development and severity of experimental tuberculosis in animals. Negre, Berthelot, and Bretey (2) were able to retard the appearance of tuberculosis lesions in guinea pigs by the injection of the ethyl esters of a series of fatty acids. Recently, Hedgecock (3) has reported that the oral administration of a diet containing the total fatty acids of coconuts also retarded the development of experimental tuberculosis in animals. Some fats and fatty acids, on the other hand, may enhance the development of experimental tuberculosis in animals. Since streptomycin is a base and has the ability to combine with fatty acids, it was thought worthwhile to make compounds of this nature for test purposes.

The fatty acid salts studied, the caprylate, undecylate, and propionate salts of both streptomycin and

dihydrostreptomycin were prepared by electro dialyzing the sulfates or hydrochlorides to the corresponding bases (4). The streptomycin base collected at the cathode was then titrated to a pH of 6.5-7 with the respective fatty acid. For the more insoluble fatty acids this titration was accomplished by the addition of a few drops of ethanol followed by slow addition of the fatty acid with periodic agitation in a high speed Waring Blendor as the desired pH was approached. The material was finally filtered to remove excess streptomycin fatty acid salt, leaving a saturated filtrate.

The fatty acid salts prepared by this method were tested for inhibition of the growth of 56 species of bacteria representing 17 genera. Included as controls were streptomycin calcium chloride complex and dihydrostreptomycin sulfate. The medium used was yeast beef broth (Difco). The ranges of the minimal inhibitory concentrations for the species in the various genera are tabulated in Table I. It can be readily seen that, as previously reported by Rake *et al.* (5), various members of the genus *Salmonella* are more resistant to dihydrostreptomycin than to streptomycin. The species of mycobacteria tested, *smegmatis*, *phlei*, and *avian*, all show a high sensitivity to the salts under study. In some of the genera there exists a wide variation in the sensitivity of the individual species to the same salt. It is apparent also that there is a considerable but less marked difference in the sensitivity of the same species to the different compounds. These differences indicate that the anionic portion of the molecule may affect materially the activity of streptomycin and dihydrostreptomycin against certain strains of bacteria. This is strikingly shown in the next experiment in which all eight salts were tested for their ability to prevent the increase in resistance of a strain of *S. typhosa* shown by previous studies (6) to have the ability of rapidly increasing in resistance to streptomycin. Serial dilutions of the eight salts were made in standard methods broth, pH 7.8 to 8. All dilutions were then inoculated with standard methods broth containing 1% of a 24-hour broth culture of *S. typhosa*. These were then in-

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

cubated overnight at 37°C and the tube containing the largest concentration of the salt which showed growth was used as the inoculum for the next series of dilutions. This was continued for 22 transfers. In Table II is shown the initial sensitivity of *S. typhosa* to the eight salts, and the sensitivity obtained on the 22nd transfer.

It can be seen that the strain of *S. typhosa* used in these studies increased in resistance to streptomycin calcium chloride complex and to dihydrostreptomycin sulfate to a far greater extent than to the fatty acid salts used. The increase in resistance to streptomycin caprylate and undecylenate was less than with any of the other salts tested.

In order to determine the specificity of the resistance developed, the strains of *S. typhosa* made resistant to the fatty acid salts of streptomycin and to streptomycin calcium chloride complex were tested for their resistance to each of the other salts. For comparative purposes, streptomycin sulfate and streptomycin hydrochloride were included. The results are shown in Table III.

It will be noted that when a strain of *S. typhosa* is made resistant to 5000 µg/ml of the calcium chloride complex salt of streptomycin, its resistance to the fatty acid salts was found to be considerably less. In the case of the undecylenate and caprylate salts, this resistance was less than 100

µg/ml. The propionate salt, which incidentally is the most soluble of the three fatty acid salts studied, caused inhibition of growth of *S. typhosa* at a concentration of 187 µg/ml, a somewhat higher level. It was necessary, however, to utilize 625 µg/ml of streptomycin sulfate and 5000 µg/ml of the streptomycin hydrochloride to cause inhibition of *S. typhosa* which had been made resistant to 5000 µg/ml of the calcium chloride complex salt of streptomycin. Except in the case of the propionate salt, whenever *S. typhosa* was made resistant to

TABLE II
Increase in resistance of *S. Typhosa* to Fatty acid salts of streptomycin and dihydrostreptomycin

HYDROCHLORIDE	5000	625	625	312

the fatty acid salts these organisms were always found to be considerably more resistant to the streptomycin salts commercially available. It is of interest that an organism made resistant to 5000 $\mu\text{g}/\text{ml}$ of the calcium chloride complex salt of streptomycin, although showing the same resistance to streptomycin hydrochloride, was found to have a resistance to only 625 $\mu\text{g}/\text{ml}$ of streptomycin sulfate. These results, coupled with those obtained with the fatty acid salts, support the conclusion that the anionic portion of the streptomycin and dihydrostreptomycin molecules may markedly influence the development of resistance of organisms to these drugs.

In order to determine the acute intravenous toxicity of the six fatty acid salts under study,

the LD₅₀ of each was determined in 20-gm. mice. For control purposes, the calcium chloride complex salts of streptomycin and dihydrostreptomycin sulfate were similarly tested. The results and also solubility data are tabulated in Table IV where it will be noted that the fatty acid salts of streptomycin are all of the same order of toxicity, approximately 1700–2000 $\mu\text{g}/20\text{-gm. mouse}$, in contrast to 3350 $\mu\text{g}/20\text{-gm. mouse}$ for the calcium chloride complex salt. Similar figures (approximately 2000 $\mu\text{g}/20\text{-gm. mouse}$) were obtained for the caprylate and undecylenate salts of dihydrostreptomycin, while the toxicity of propionate salt of dihydrostreptomycin was of the same order of toxicity as dihydrostreptomycin sulfate.

DISCUSSION

It is apparent from the present study that the bacterial spectra of the fatty acid salts of streptomycin and dihydrostreptomycin are approximately the same as those for the presently available commercial salts of these drugs. The genera of those organisms susceptible to the commercially available salts were found to be equally susceptible to the fatty acid salts of streptomycin and dihydrostreptomycin, respectively. The individual species of bacteria which were found to have a low resistance to the commercially available streptomycin were found to have a similar low resistance to the fatty acid salts of this drug. Those found to have a high resistance to commercially available streptomycin (e.g. *Salmonella*) were found to have a

TABLE IV
Acute intravenous toxicity of various salts of streptomycin and dihydrostreptomycin

Streptomycin salt	LD50 μg/20 gm mouse	Solubility in H ₂ O
Calcium chloride complex	3350	mg/ml Very soluble

Propionate	2600	Very soluble

* Salt used as diluent.

† Tested at 2 ml. injected in saline solution.

similar resistance to the fatty acid salts of streptomycin. A similar pattern was demonstrated with dihydrostreptomycin sulfate and the fatty acid salts of dihydrostreptomycin.

When attempts were made to demonstrate the increase in resistance of a strain of *S. typhosa* to the fatty acid salts of streptomycin and dihydrostreptomycin, using as controls the calcium chloride complex salt of streptomycin and dihydrostreptomycin sulfate, it was quite obvious that this organism developed resistance to a considerably less degree to the fatty acid salts than to the commercially available salts of streptomycin and dihydrostreptomycin.

Studies of resistant strains of *S. typhosa* developed through growth in increasing concentrations of the various salts of streptomycin indicate that the resistance developed is specific to a certain degree. A strain of *S. typhosa* made resistant to 5000 $\mu\text{g/ml}$ of the calcium chloride complex salt of streptomycin, although having the same resistance to streptomycin hydrochloride, had only one-eighth as much resistance to streptomycin sulfate, less than one-fiftieth the resistance to the caprylate and undecylenate salts of streptomycin, and approximately one-twenty-fifth the resistance to the propionate salt. Twenty-two transfers of *S. typhosa* in increasing concentrations of the undecylenate, caprylate, and propionate salts of streptomycin resulted in the development of resistance of 30 $\mu\text{g/ml}$, 80 $\mu\text{g/ml}$ and 400 $\mu\text{g/ml}$, respectively, indicating that the resistance of *S. typhosa* to these salts develops with some difficulty as compared to the resistance developed by this organism when grown in increasing concentrations of the calcium chloride complex salt of streptomycin. It should be pointed out also that when *S. typhosa* is made resistant to the undecylenate and caprylate salts of streptomycin, the resistance developed concomitantly to the streptomycin salts commercially available is considerably greater. Thus, a strain of *S. typhosa* made resistant to 30 $\mu\text{g/ml}$ of the undecylenate salt of streptomycin was found to be resistant to from 312 to 625 $\mu\text{g/ml}$ of streptomycin sulfate, streptomycin hydrochloride, and the calcium chloride complex salt of streptomycin. Since in these studies an intensive effort was made to increase the resistance of a strain of *S. typhosa* to the various streptomycin

salts utilized, it is quite possible that under ordinary conditions little or no resistance would develop to the fatty acid salts. The results of these studies indicate the preparation of new streptomycin and dihydrostreptomycin compounds might well lead to the finding of drugs with improved usefulness. The fatty acid salts are being tested for their effect on experimental infections in animals and for their inhibitory action against tubercle bacilli isolated from cases treated with commercially available salts of streptomycin and dihydrostreptomycin.

It is apparent from the acute toxicity studies of the fatty acid salts of streptomycin and dihydrostreptomycin that the fatty acid salts of streptomycin have approximately twice the acute toxicity of the calcium chloride complex salt of streptomycin, while the propionate salt of dihydrostreptomycin has approximately the same toxicity as dihydrostreptomycin sulfate, and the caprylate and undecylenate salts of dihydrostreptomycin have only a slightly greater toxicity than dihydrostreptomycin sulfate. It should be pointed out that some difficulty was encountered in determining the acute intravenous toxicity because of the insolubility of the caprylate and undecylenate salts of both streptomycin and dihydrostreptomycin.

SUMMARY AND CONCLUSIONS

1. The bacterial spectra of the fatty acid salts of streptomycin and dihydrostreptomycin are approximately the same as that of the streptomycin and dihydrostreptomycin salts commercially available.
2. *S. typhosa* develops resistance to the fatty acid salts of streptomycin and dihydrostreptomycin at a slower rate and to a considerably less degree than to the commercially available salts of these drugs.
3. When *S. typhosa* is made resistant to high concentrations of the calcium chloride complex salt of streptomycin, this organism has relatively low resistance to the fatty acid salts of streptomycin, and, conversely, when *S. typhosa* is made resistant to relatively low concentrations of the fatty acid salts of streptomycin, this organism has a relatively high resistance to the commercially available salts of streptomycin.

4. The anionic portion of the streptomycin and dihydrostreptomycin molecules markedly affects the ability of an organism to develop resistance to these drugs.

5. The fatty acid salts of streptomycin studied are from 1.5 to 2.0 times as toxic as the calcium chloride complex salt of streptomycin when tested intravenously in mice, while the fatty acid salts of dihydrostreptomycin are of approximately the same order of toxicity as dihydrostreptomycin sulfate.

THE EFFECTS OF NORMAL HORSE SERUM ON THE *IN VITRO* ACTIVITY OF TYROTHRIN¹

BY ROBERT J. REEDY AND STANLEY W. WOLFSON

(From the Food and Drug Administration, Federal Security Agency, Washington, D. C.)

Tyrothricin, discovered by Dubos, is an antibiotic product of *Bacillus brevis*. Its antibacterial action against a wide variety of Gram-positive organisms can be demonstrated by both *in vitro* and *in vivo* tests. As a therapeutic agent, it has been restricted to topical use because of its inherent toxicity on parenteral administration.

Tyrothricin is composed of two fractions, gramicidin and tyrocidine. Except in relatively large amounts tyrocidine has little or no activity against most of the Gram-positive bacteria. On the other hand, gramicidin in very minute amounts exerts a marked antibacterial activity against many of these organisms, and is therefore largely responsible for the major activity of tyrothricin.

As tyrothricin is used in the form of ointments, emulsions, troches, etc. for topical therapy, and as there is some controversy in the literature concerning the effect of serum on the bacteriostatic efficacy of this antibiotic, it seemed desirable to investigate the extent of its reduced activity, if any, in the presence of serum. Dubos (1) stated that the effect of gramicidin is inhibited "only to a small extent by serum, tissue exudates or peptones." Rammelkamp (2), however, noted that serum, exudates and feces markedly inhibit the activity of tyrothricin, and that approximately 100 times the amount of this antibiotic was required to exert an anti-streptococcal activity in their presence. Hotchkiss (3) reported that gramicidin is mildly inhibited by the presence of serum, but that tyrocidine possesses little activity in its presence. Henderson (4) noted that gramicidin, in contrast to tyrocidine, is not affected by soluble proteins, such as serum albumin, "in any concentration," in fact "its activity seems enhanced by serum albumin," a statement he attributes to Dubos.

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

METHODS

In our tests, two organisms and three media were employed. The organisms were *Streptococcus fecalis* (M-19) and *Micrococcus pyogenes* var. *aureus* (F.D.A. No. 209). The fecal streptococcus was selected for its high degree of sensitivity to this antibiotic, and *S. aureus* for its prevalence in skin lesions. Three broth media chosen for their different nutritive qualities were used: Edamin (0.8%), Bacto Peptone (1.0%), and Bacto Brain Heart Infusion (3.7%). Cultures in these media incubated at 37° C. were transferred daily, and 1% suspensions utilized in the assay inoculum. The method used for testing the sensitivity of the organisms to tyrothricin was a decimal dilution technic² where varying amounts of an alcoholic solution of tyrothricin were brought into direct contact with the organisms suspended in the assay broths. Bacteriostatic endpoints were determined by visual inspection of the tubes for presence or absence of growth. The tyrothricin used was the accepted standard composed of a mixture of 80% crystalline tyrocidine hydrochloride and 20% crystalline gramicidin in a concentration of 5 mgms. per ml., dissolved in 95% ethyl alcohol. In the assay, the volume of alcohol never exceeded 0.2 ml. per 5 ml. of broth to eliminate the possibility of alcohol affecting the growth of the organisms. All titrations were made in triplicate. In certain instances, where high concentrations of tyrothricin were employed with the fecal streptococcus in the presence of 5% serum, the endpoints could not be determined with any degree of accuracy because of the presence of a precipitate. In such cases the endpoint was determined by the use of a brom thymol blue indicator, growth being indicated by an alkaline reaction. When it became necessary to determine bacteriostasis with the staphylococcus under the same conditions, a nitrate reduction method (5) was employed, growth being indicated by a positive color reaction for nitrite.

RESULTS

Figure 1 illustrates the minimal inhibitory concentrations of tyrothricin required for the two organisms in the three media with and without serum. It can be noted that in the absence of serum the amounts of tyrothricin necessary to cause complete inhibition of *S. fecalis* were 0.01 microgram when Edamin was employed, and 0.1 microgram when both Bacto Peptone and Bacto

² This information will be published in the near future.

INFLUENCE OF SERUM ON THE BACTERIOSTATIC
ENDPOINTS OF TYROTHRICIN

FIG. 1. INFLUENCE OF SERUM ON THE BACTERIOSTATIC ENDPOINTS OF TYROTHRICIN

Brain Heart Infusion broths were used. Upon the addition of 5% normal horse serum to the Edamin broth, it was necessary to use 1,000 times (10.0 micrograms) as much tyrothricin to produce the same degree of bacteriostasis. When serum was added to Bacto Peptone, the amount of tyrothricin necessary to produce the same degree of bacteriostasis was increased 250 fold (25.0 micrograms). A 40-fold increase in the amount of tyrothricin was required to produce bacteriostasis in the presence of serum with the Bacto Brain Heart Infusion broth (4.0 micrograms). As will

be noted in Figure 1, the staphylococcus proved to be approximately 150 times more resistant to the action of tyrothricin than the fecal streptococcus. In spite of this, however, the addition of serum markedly increased the amount of tyrothricin necessary to produce bacteriostasis. Both crystalline gramicidin and crystalline tyrocidine have been tested for their bacteriostatic activity in Edamin broth with and without 5% serum. The streptococcus was inhibited by 20.0 micrograms of tyrocidine in the absence of serum while 200 micrograms were required when serum

was present. On testing the gramicidin fraction with this organism 0.002 microgram was found to be necessary to achieve bacteriostasis in the absence of serum. In its presence, the streptococcus required 2.0 micrograms. Unusual results were obtained when the staphylococcus was tested with tyrocidine. It was found that this fraction was not inhibited by the presence of serum at a concentration of 300 micrograms or more. This amount of tyrocidine was the minimum amount necessary to produce bacteriostasis in the presence and absence of serum. A similar effect was not noted for the gramicidin fraction, however, as 0.2 microgram was required in the absence of serum while 80 micrograms were necessary in its presence.

DISCUSSION

In demonstrating the sensitivity of these organisms to the components of tyrothricin (gramicidin and tyrocidine) it was found that in Edamin broth the fecal streptococcus exhibited a susceptibility to 0.002 microgram of crystalline gramicidin. Its growth was unaffected by 15.0 micrograms of crystalline tyrocidine in this medium. The staphylococcus showed a sensitivity to 0.2 microgram of crystalline gramicidin yet resisted 300 micrograms of crystalline tyrocidine. Because of the vast differences in sensitivity of these organisms to the two components of tyrothricin, any effect of serum on this antibiotic can only be demonstrated by its action on the gramicidin fraction. Although the loss of activity of tyrothricin is attributed to the interference with the gramicidin fraction, there is some indication, however, that when large concentrations (400 micrograms or more) of tyrothricin are present, the tyrocidine fraction may play an important part in antibacterial activity. Although, contrary to reports, we have shown the activity of gramicidin to be greatly reduced by

as little as 5% serum, it cannot be definitely stated that this is entirely due to the direct effect of serum on the gramicidin. From the figures obtained there is some evidence that the serum possibly supplied an added growth factor that might have played a part. Whatever the reason, it is a fact that serum does greatly reduce the activity of tyrothricin tested *in vitro*. It may well be inferred, therefore, that in the presence of undiluted serum exuding from a trauma, where only a thin film of applied tyrothricin is permitted to come into direct contact, its antibiotic activity may be reduced to a point of minor therapeutic value.

SUMMARY AND CONCLUSIONS

It has been shown that the addition of 5% normal horse serum markedly reduced the activity of tyrothricin. The amount of tyrothricin necessary to inhibit the test organisms was markedly influenced by the composition of the medium. From the data obtained it can be concluded that the effective component of tyrothricin is gramicidin. Contrary to published reports, we have found that in inhibitory concentrations tyrocidine is not affected by serum when the test organism is *Staphylococcus aureus*.

COMPARISON OF THE ACTION OF STREPTOMYCIN, POLYMYXIN B, AUREOMYCIN AND CHLOROMYCETIN ON *H. PERTUSSIS*, *H. PARAPERTUSSIS*, *H. INFLUENZAE* AND FIVE ENTERIC STRAINS OF GRAM-NEGATIVE BACILLI^{1,2}

By HATTIE E. ALEXANDER, GRACE LEIDY, AND WINIFRED REDMAN

(From the Babies Hospital and the Department of Pediatrics, Columbia University College of Physicians and Surgeons)

Our recent investigations (1) suggest that knowledge of two factors operating *in vitro*—speed of lethal action on sensitive cells and frequency of resistant mutants—offers a reliable basis for predicting the therapeutic efficacy of streptomycin against eight different species of gram-negative bacilli. The data are summarized in Table I. The organisms responsible for infections which have been successfully treated with streptomycin—*H. influenzae*, *E. coli* and *H. pertussis*—have a low incidence of mutants which resist the action of 25 mcg. (micrograms) and 100 mcg. of streptomycin per c.c. In addition, their sensitive cells are killed rapidly by concentrations of streptomycin safely maintained in body fluids (10 mcg. per c.c.). On the other hand, in those infections in which streptomycin has not been found effective therapeutically a concentration of 10 mcg. per c.c. is not rapidly bactericidal for the sensitive cells, and the frequency of mutants resistant to 25 mcg. of streptomycin per c.c. is relatively high—10,000 to 100,000 times the rate of comparable mutants in successfully treated infections (Table I). In *Shigella* and *H. parapertussis* infections, in which streptomycin has not been clinically evaluated, one would predict success in the former and failure in the latter.

In an effort to improve therapeutic results in those infections in which streptomycin has failed therapeutically, either uniformly or as a result of emergence of resistance, three newer antibiotics—polymyxin B, aureomycin and chloromycetin—have been compared with streptomycin in their

action on the same eight species of gram-negative bacilli.

For this purpose three features of their activity have been studied:

1. The minimal concentrations of each agent needed to prevent growth completely over a 48-hour incubation period. A 24-hour period was used for aureomycin for most organisms.
2. The nature of their action on the eight species—primarily bacteriostatic or bactericidal—and the speed of any lethal action.
3. Predictable limitation of their therapeutic efficacy as a result of emergence of resistance and their influence on streptomycin-resistant mutants.

I. *Minimal effective concentrations*

A simple *in vitro* test, which provided valuable information of streptomycin action on these species, has been used to study the influence of polymyxin B, aureomycin and chloromycetin. This procedure determined the lowest concentration which completely prevented the growth of an inoculum of one to ten million organisms on an optimal agar medium after 48 hours' incubation. Because of the alleged lability of aureomycin *in vitro* the minimal effective concentration of this agent was assessed at 24 hours.

The results are seen in Table II. It is apparent that those organisms which require more than 25 mcg. of streptomycin per c.c. to prevent completely growth under the circumstances described are the causes of infections which have not been treated successfully with streptomycin. Polymyxin B appears to be the most efficient of the four agents and the broadest in its action. Aureomycin and chloromycetin are about equal in their range of action; the growth of each of the eight bacterial species is completely prevented by less than 25 mcg. per c.c. save for *Ps. aeruginosa*; the majority exhibited a high degree of sensitivity.

<i>Ps. aeruginosa</i>	10 ⁻⁵ to 10 ⁻⁶	10 ⁻⁷ to 10 ⁻⁸	10 ⁻¹⁰	0	4 hrs

* - Not primarily bactericidal

II. Speed of lethal action

Polymyxin B, aureomycin and chloromycetin have been compared with streptomycin in the speed of their lethal action on small populations (approximately 10,000 to 30,000 organisms per c.c.) in environments which will permit growth. After exposure to the antibiotics for two, six and

24 hours, samples of the broth cultures were examined for the number of viable organisms per c.c. by seeding into appropriate media in pour plate preparations after removal of any inhibitory concentration of the antibiotic, either through dilution or centrifuging and resuspending in normal broth. Table III presents the results on each of the eight species. The per cent of viable organisms remaining after exposure for six hours to two different concentrations of each of the antibiotics is listed.

It is apparent that streptomycin is primarily bactericidal in 10 mcg. per c.c. only against species for which it has been shown to be therapeutically effective. Polymyxin B exerts a rapid lethal action in concentrations of both 1 mcg. and 10 mcg. per c.c. Cultures of all species save for 0.07 per cent in *Salmonella* were sterile after two hours; shorter exposure times have not been studied. Chloromycetin in 10 mcg. per c.c. exerts a more rapid bactericidal action against *H. pertussis* and *H. paraptussis* than does aureomycin; against *H. influenzae* and *S. typhosa* the two agents are equal in the speed of their lethal action. Both aureomycin and chloromycetin are bacteriostatic for all of the other species with the exception of *Ps. aeruginosa*; in a concentration of 100 mcg. per c.c. aureomycin exerts a greater lethal action than does chloromycetin. On the other hand the

<i>H. PARAPTUSSIS</i>	>25	5	3	5->10

* 20 hour studies were run for *H. pertussis* and *H. paraptussis*.

results of exposure for 24 hours, not listed here, show that stasis of growth by chloromycetin persists through 24 hours in cultures of all of these organisms save for *Ps. aeruginosa*, and the number of viable cells even decreases significantly, whereas the static effect of aureomycin is seen after 24 hours only against *Shigella* and *S. typhosa*; these results may only reflect the deterioration of aureomycin. However the persistence of bacteriostasis with some organisms suggests that other factors are playing a role.

Ps. aeruginosa is not even inhibited by a six-hour exposure to streptomycin, chloromycetin or aureomycin in a concentration of 10 mcg. per c.c., whereas polymyxin B in a concentration of 1 mcg. per c.c. is bactericidal within two hours.

The greater bactericidal action of 100 mcg. per c.c. of streptomycin is worthy of emphasis since in infections of the meninges and urinary tract a comparable concentration can be maintained in these fluids without damage in most patients.

III. Resistance problem

The study of the limitation of therapeutic efficacy of these agents by the phenomenon of resistance was approached in two ways: 1) examination of large populations for presence of cells resistant to these antibiotics, and 2) examination of

E. SHIMAKOV

their action on streptomycin-resistant mutants of each of these species.

It has already been reported (2-4) that mutants resistant to 1000 mcg. of streptomycin per c.c. may be easily demonstrated in large populations of each of the eight species; mutants resistant to 25 mcg. and 100 mcg. of streptomycin per c.c. are uniformly present in smaller populations of the species against which this antibiotic has not been effective therapeutically (1).

Large populations, 60 to 600 billions, of each of the eight species have been examined for presence of cells resistant to polymyxin B, 10 mcg. and 100 mcg. per c.c. and chloromycetin 10 mcg. per c.c.; the supply has not permitted study of a higher concentration. *H. pertussis* and *H. parapertussis* have been examined for cells resistant to 10 mcg. and 100 mcg. of aureomycin per c.c.

It was not possible to demonstrate cells resistant to 100 mcg. per c.c. of polymyxin B in any species by this method, and only in *Salmonella* and *Ps. aeruginosa* was it possible to demonstrate a minute fraction of cells resistant to 10 mcg. per c.c.; when a few of the colonies of these two species which formed in agar containing 10 mcg. per c.c. were tested for their sensitivity to this concentration only an occasional colony grew in polymyxin B agar (10 mcg. per c.c.) but growth was normal on control medium.

While a few colonies grew when large populations of *E. coli*, *Salmonella* and *S. typhosa* were seeded in pour plate preparations of agar containing 10 mcg. per c.c. of chloromycetin, none of them on subculture grew on chloromycetin agar (10 mcg. per c.c.).

The investigation of resistance of these newer agents is still in progress but it is already apparent that resistance to polymyxin B and chloromycetin differs from streptomycin resistance; the data suggest that emergence of resistance will play a less important role in therapy.

The influence of polymyxin B, chloromycetin and aureomycin on cells highly resistant to streptomycin is shown in Table IV for each of the eight species. The sensitivity of these streptomycin-resistant strains does not differ significantly from those strains which are sensitive to streptomycin. Therefore it is apparent that the mechanism of action of each of these agents differs from the mode of action of streptomycin.

These data suggest a number of clinical applications. Polymyxin B would be the treatment of choice for all of these infections, but its toxic action precludes its clinical use unless the injurious substance can be removed without altering the antibacterial action. A final assessment of aureomycin *in vitro* must await additional factual data. Chloromycetin because of absence of toxic manifestations, its rapid lethal action on *H. influenzae* and *H. pertussis* and the rarity of resistant mutants warrants a clinical trial in these infections. In *E. coli* and *Shigella* infections there

is reason to anticipate a more rapid elimination of the organisms by the combined action of sulfadiazine and streptomycin than by aureomycin or chloromycetin alone. In *Salmonella* and *S. typhosa* infections, either chloromycetin or aureomycin should be a more effective agent than streptomycin. For *Ps. aeruginosa* infections we can expect little therapeutic value from streptomycin, aureomycin or chloromycetin used as a single agent if concentrations in the body fluids do not exceed 10 mcg. per c.c. The results suggest that the combined action of streptomycin and aureomycin may prove of therapeutic value in *Ps. aeruginosa* infections of body fluids in which concentrations of 50 mcg. to 100 mcg. per c.c. can be maintained with safety. In *H. paraptussis* infections chloromycetin should prove to be the treatment of choice.

EXPERIMENTAL STUDIES ON THE ACTION OF STREPTOMYCIN, AUREOMYCIN, AND CHLOROMYCETIN ON BRUCELLA^{1,2}

BY ELLARD M. YOW AND WESLEY W. SPINK

(From the Division of Internal Medicine, University of Minnesota Medical School, Minneapolis)

The use of streptomycin in the treatment of brucellosis revealed that most of the patients failed to respond satisfactorily to its administration, and among those who did respond, relapses almost always followed (1). It was subsequently observed that when sulfadiazine was given simultaneously with streptomycin, the result was much more encouraging (2-4). However, this combination was also followed by relapses (5). *Brucella* could be recovered after treatment from the blood of approximately 25 per cent of the patients with infections due to *Br. abortus* and 45 per cent of those with disease due to *Br. melitensis*.

In this clinic the failure of streptomycin and sulfadiazine to eradicate *Brucella* consistently from the tissues prompted the study of why such a therapeutic combination failed, and stimulated the search for more effective antibrucella agents. The problem was approached by *in vitro* studies, animal experiments, and, finally, by the clinical trial of newer antibiotic agents. This report is concerned primarily with the results of the *in vitro* experiments.

I. STREPTOMYCIN AND DIHYDROSTREPTOMYCIN

In vitro Sensitivity of *Brucella*

Forty-one strains of *Brucella* recently isolated from patients were tested for sensitivity to streptomycin and dihydrostreptomycin.

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

² This investigation was supported (in part) by a research grant from the Division of Research Grants and Fellowships of the National Institutes of Health, United States Public Health Service, and by a grant from the Lederle Laboratories. The aureomycin was supplied by the Lederle Laboratories; the dihydrostreptomycin, by E. R. Squibb Company; polymyxin, by the Stamford Research Laboratories, American Cyanamid Company; bacitracin and Q-19, by the Upjohn Company; and chloromycetin, by Parke, Davis and Company.

Method: Solutions of streptomycin and dihydrostreptomycin were prepared by adding 10 ml. of physiologic saline solution to 1.0 gram of base of the drugs. The stock solution was stored at 4° C. and was diluted to a concentration of 1000 or 100 µg. per ml. immediately before the sensitivity tests were performed. To each of 12 test tubes (12 × 100 mm.), except the first, was added 0.5 ml. of tryptose phosphate broth. The first two tubes were inoculated with 0.5 ml. each of the test solution of streptomycin or dihydrostreptomycin. Two-fold dilutions of the drug were made by transferring 0.5 ml. of the mixture in the second tube to the third tube, and so on, through the 11th tube. The 12th tube contained only broth and organisms. Each of the 12 tubes was then inoculated with 1.5 ml. of a 1:100 dilution of a 24-hour culture in tryptose phosphate broth. Thus, the first tube contained a 1:4 dilution of the test solution of the antibiotic; the second, 1:8; third, 1:16, through the 11th, which contained a 1:4096 dilution. The cultures of *Br. abortus* were incubated for 48 hours at 37° C. in an environment containing a 10 per cent concentration of carbon dioxide, while the strains of *Br. suis* and *Br. melitensis* were subjected to normal atmospheric conditions. At the end of this time, the tubes were examined for gross turbidity and the contents of each tube streaked on tryptose agar. The sensitivity of the organism was reported as the minimum concentration of streptomycin or dihydrostreptomycin required to kill all the organisms.

Results: Thirteen strains of *Br. abortus*, ten of *Br. melitensis*, and one of *Br. suis*, all isolated before being exposed to streptomycin, were found to be sensitive to concentrations between 1.0 and 2.5 µg. of streptomycin and dihydrostreptomycin per ml. The results are presented in Tables I and II.

The Bactericidal Action of Streptomycin on Brucella

The effect of streptomycin on the multiplication and viability of *Brucella* was studied in the following manner.

Methods: A saline suspension of organisms, equal in turbidity to a barium sulfate No. 1 standard, was prepared from a 48-hour agar culture of *Br. abortus*. Three tubes containing 10 ml. of tryptose phosphate broth were inoculated with 0.05 ml. of the bacterial suspension so that the final concentration of organisms was approximately 5,000,000 bacteria per ml. Sufficient streptomycin was added to each of two tubes to make a concentration of

10 μg. per ml. in one tube and 20 μg. per ml. in the other. The third tube was used as a control. The same procedure was carried out using cultures of *Br. melitensis* and *Br. suis*. The tubes were incubated under the proper tension of carbon dioxide at 37° C., and a standard loopful of the broth from each tube was subcultured on streptomycin-free agar at 15-minute intervals during the first hour, at three and six hours after inoculation, and then daily for 14 days. The subcultures were incubated for 96 hours and examined for growth. The broth cultures were inspected for evidence of growth turbidity at the time of each subculture.

Results: No evidence of bacterial multiplication appeared in the broth cultures containing streptomycin, while in the control tubes there was a turbid growth at the end of the first 24 hours of incubation. No viable *Brucella* could be recovered from the tubes containing streptomycin after three hours of incubation, whereas the control cultures contained living organisms throughout the 14 days of observation (see Tables III and IV).

cause of the failure of the antibiotic in the treatment of human infections. The most acceptable theory of the origin of streptomycin-resistant strains of bacteria is that they arise from innately resistant organisms normally present in small numbers in every large population of a sensitive strain (6). The presence of naturally occurring streptomycin-resistant organisms in sensitive strains of *Brucella* was demonstrated by exposing

large bacterial populations to varying concentrations of streptomycin.

Method: A concentrated suspension of organisms was prepared by heavily inoculating a large tryptose agar

slant with a culture of *Brucella*. After 48 hours of incubation, the bacteria were washed from the slant with 1.0 ml. of tryptose phosphate broth. The suspension of organisms was spread evenly over the agar surface of bottles, prepared by adding 60 ml. of melted agar to 16

Survival of Variants of *Brucella Abortus* Resistant to Streptomycin

524

FIG. 1

oz. oval prescription bottles with screw caps. The bottles were incubated with the inoculated agar surface down for 48 hours, and then the bacterial growth was resuspended in 5 ml. of broth. Bacterial counts on the suspension of organisms were performed with a photoelectric colorimeter by comparing the turbidity of a 10^{-3} dilution to a barium sulfate standard No. 1. The concentration of bacteria was adjusted to approximately 100 billion organisms per ml. and then exposed to varying concentrations of streptomycin. Eleven pour plates were prepared, using 1.0 ml. of the bacterial suspension, 9.0 ml. of tryptose agar, and sufficient concentrations of streptomycin to make final concentrations of 1.0, 2.5, 5.0, 10, 50, 100, 500, 1,000, 5,000, 10,000, and 100,000 $\mu\text{g. per ml.}$ Each experiment was performed in triplicate and the plates were incubated in jars at 37°C. Colony counts were performed weekly for a month.

Results: The number of the surviving streptomycin-resistant variants decreased very rapidly as the concentration of streptomycin increased from 1.0 to 5.0 $\mu\text{g. per ml.}$, then more gradually to a concentration of 10,000 $\mu\text{g. per ml.}$, after which

there were no surviving variants. Streptomycin survival curves for *Br. abortus* are shown in Figure 1, and for *Br. suis*, in Figure 2.

Some of the streptomycin-resistant colonies were found to be largely dependent upon streptomycin for growth. The dependency of the colonies upon streptomycin was determined by adding suspensions of the colonies to pour plates with and without the addition of 100 $\mu\text{g.}$ of streptomycin per ml. The resistant colonies grew equally well in the presence or absence of streptomycin, whereas the dependent colonies multiplied only in the plates containing the antibiotic. These dependent strains would grow if streaked heavily on streptomycin-free agar, but not as luxuriously as non-dependent strains. Streptomycin-dependent strains of *Brucella* grew equally well in the presence of dihydrostreptomycin, and strains dependent upon dihydrostreptomycin multiplied in media containing streptomycin. Media containing

aureomycin or chloromycetin did not support the growth of streptomycin-dependent strains.

Sensitivity of Strains of *Brucella* Isolated after Streptomycin Therapy

Streptomycin resistance as a cause of therapeutic failure in cases of brucellosis was investigated, first, by determining the sensitivity of the strains isolated after therapy as compared to the sensitivity of the strains isolated from the same patient before therapy; and, secondly, by comparing the distribution and number of the resistant variants occurring in these strains of *Brucella*.

Fifteen strains of *Brucella* isolated after streptomycin therapy were tested for sensitivity to streptomycin. Seven strains of *Br. abortus* and six strains of *Br. melitensis* cultured after combined sulfadiazine and streptomycin therapy showed no change in sensitivity to streptomycin. One strain of *Br. abortus* obtained after treatment

with only streptomycin was studied by Hall and Spink (7) and was found to have increased in resistance from 1.0 $\mu\text{g.}$ per ml. to 10,000 $\mu\text{g.}$ per ml. One strain of *Br. melitensis*, isolated after combined streptomycin and sulfadiazine therapy, changed in sensitivity from 2.5 $\mu\text{g.}$ to 50,000 $\mu\text{g.}$ of streptomycin per ml.

The two strains of *Brucella* which developed resistance to streptomycin were studied for evidence of streptomycin dependency. The strain of *Br. melitensis* did not depend upon the presence of streptomycin for growth, but the resistant strain of *Br. abortus* contained predominantly colonies that were smaller than normal and grew on streptomycin-free agar only when a heavy inoculum was used. The growth of the small colonies was greatly enhanced by the addition of from 50 to 1,000 $\mu\text{g.}$ of streptomycin per ml. (7).

The number of the resistant variants present in the strains isolated after therapy was compared

is identical to the curve of the strain cultured from the same patient before therapy.

In order to obtain data on the number of resistant organisms present in a large number of strains of *Brucella*, these strains were exposed to an arbitrary concentration of 100 µg. of streptomycin per ml. These studies revealed that the number of variants present in strains obtained after therapy did not vary significantly from the number of survivors present in strains isolated before therapy. The number of resistant survivors found in the cultures of *Br. melitensis* was greater than the number of survivors present in strains of *Br. abortus* (Tables V and VI).

Other properties of the strains of *Brucella* recovered from patients after the completion of streptomycin therapy were studied. There were no changes in the gross colony or growth characteristics, or were changes in cell morphology noted. There were no differences in the susceptibility of these strains to the bactericidal effect of normal human serum or convalescent brucellosis serum, nor in their sensitivity to other antibiotics.

II. AUREOMYCIN

Studies with aureomycin were approached, first, by investigating the *in vitro* activity of the antibiotic against the three species of *Brucella*; secondly, by an evaluation of its action against experimentally produced infections in the chick embryo, mouse, and guinea pig; and finally, by its clinical trial in the treatment of patients with brucellosis (8, 9). The results of the *in vitro* experiments will be summarized in this report.

In vitro Sensitivity

Forty-four strains of *Brucella*, including 23 strains of *Br. abortus*, 20 strains of *Br. melitensis*, and one strain of *Br. suis*, were tested for sensitivity to aureomycin.

Method: The broth dilution method was used and varied slightly from that described for the determination of streptomycin sensitivity. The stock solution of aureomycin was prepared by adding 20 ml. of a sterile saline solution to a vial containing 20 mg. of aureomycin hydrochloride. The stock solution was stored at 4° C. for as long as a month and diluted to a concentration of 100 µg. per ml. the day the sensitivity tests were performed. In contrast to the values expressed for streptomycin and dihydrostreptomycin, the sensitivity of *Brucella* to aureomycin was reported as that concentration of the antibiotic required to prevent the multiplication of the bacteria, as measured by broth turbidity. The concentration actually sterilizing the cultures was determined in some of the tests by subculturing the broth from each tube on agar, and was reported as the minimal concentration of the drug from which no live organisms could be recovered.

Results: The sensitivity of the strains of *Brucella* to aureomycin varied from 0.6 to 1.5 µg. per ml., though concentrations as high as 62.5 to 125 µg. of aureomycin per ml. were required to steri-

lize the cultures (see Tables VII and VIII). Two strains of *Brucella* resistant to streptomycin showed no comparable increased resistance to aureomycin.

The Action of Aureomycin on *Brucella*

The technique of the experiment was identical to that described already for streptomycin, except that the concentrations of aureomycin employed were 1.0, 10, and 100 µg. per ml.

Results: The broth containing 1.0 µg. of aureomycin per ml. became turbid on the second day of incubation, one day later than the control. Broth turbidity developed in the tube containing 10 µg. per ml. on the fourth day, but there was no evidence of multiplication of *Brucella* in the broth containing 100 µg. of aureomycin per ml. Organisms were consistently recovered from the tubes containing 1.0 and 10 µg. per ml., but no *Brucella* were cultured from the aureomycin concentration

of 100 μ g. per ml. after the first 24 hours of incubation (see Tables IX, X and XI).

The Relation Between the Antibrucella Effect of Aureomycin and the Bactericidal Power of Human Serum

Clinical experience with aureomycin in the treatment of brucellosis reveals that the antibiotic is apparently more effective against *Brucella* in human beings than it is *in vitro* or in experimentally infected animals (9). In an effort to investigate further the mechanism of action of aureomycin and its effect on certain immune mechanisms, the relationship between the bactericidal power of human serum and the antibrucella effect of aureomycin was studied.

Method: Seventy test tubes (12 × 100 mm.) were arranged in 10 series, with seven tubes in each series. To each of the 70 tubes was added 0.25 ml. of serum. Each tube in the first series was inoculated with 0.1 ml. of a

solution of aureomycin containing 500 $\mu\text{g. per ml.}$; the tubes in the second series, with 0.1 ml. of a solution containing 250 $\mu\text{g. per ml.}$; and so on, decreasing the concentration by halves through the ninth series. No aureomycin was added to the tubes in the tenth series, which served as a control for determining the action of the serum alone against *Brucella*. The first tube in each series was then inoculated with 0.15 ml. of a suspension of a 48-hour culture of *Br. abortus*, equal in turbidity to a barium sulfate standard No. 1; 0.15 ml. of a 10^{-1} dilution was added to the second tube in each series; 0.15 of a 10^{-2} dilution, to the third tube; and so on, through the seventh tube in each series, to which was added 0.15 ml. of a 10^{-6} dilution of the suspension of *Brucella*. Thus, the total volume in each tube was 0.5 ml., and the final concentration of aureomycin in the first series of tubes was 100 $\mu\text{g. per ml.}$, through 0.39 $\mu\text{g. per ml.}$ in the ninth series. After incubating for 24 hours under 10 per cent carbon dioxide at 37°C. , the contents of each tube were subcultured on tryptose agar, using a 4 mm. wire loop. The subcultures were incubated for 96 hours and the growth recorded from + to +++++.

The experiment was performed using the serum from three normal individuals, serum from the same donors heated at 56° C. for 30 minutes, and from two patients with high agglutination titers for brucellosis. A control was performed with each experiment in which broth was substituted for the serum.

Results: In series one and two, which contained the highest concentrations of aureomycin, serum interfered with the activity of aureomycin. The bactericidal power of serum, on the other hand, was enhanced by the addition of aureomycin in proportion to the concentration of the latter. The inactivated serum had no effect in increasing the antibrucella activity of aureomycin when compared to the broth control, and convalescent brucellosis serum increased only slightly the effect of the aureomycin. The most striking antibrucella

Aureomycin concentration

present in a large bacterial population, using the method described for the isolation of streptomycin-resistant variants. A further attempt was made to develop aureomycin-resistant strains of *Brucella* by exposing the organisms to increasing concentrations of aureomycin.

Method: A 1:100 dilution in broth of a 24-hour culture of *Br. abortus* was exposed to aureomycin in concentrations from 250 to 0.25 $\mu\text{g.}$ per ml. in the manner described for the broth dilution method of determining the sensitivity of *Brucella* to aureomycin. After incubating for 72 hours, the broth-aureomycin mixture in each tube was examined for turbidity and at the same time a loopful was streaked on tryptose agar. The turbid broth containing the highest concentration of aureomycin was diluted 1:100 and reexposed to aureomycin in the same manner. This procedure was repeated at 72-hour intervals, using as the inoculum in each test the broth from the preceding test containing the highest concentration of aureomycin permitting the multiplication of the bacteria.

Results: After 16 exposures of the strain of *Br. abortus* to aureomycin, there was no significant increase in resistance, as measured by the antibiotic necessary to inhibit growth, or by that

amount necessary to kill the bacteria (see Figure 5).

Strains of Brucella Isolated after Aureomycin Therapy

One strain of *Br. abortus* and three strains of *Br. melitensis* isolated after aureomycin therapy were tested for sensitivity to the antibiotic. There were no changes in the sensitivity to aureomycin when compared to the sensitivity of the strain isolated from the same patient before therapy.

III. CHLOROMYCETIN

The observation by Ehrlich (10) and Gottlieb (11) that chloromycetin inhibited the growth of gram-negative organisms prompted the investigation of the action of his antibiotic against *Brucella*.

In vitro Sensitivity of Brucella to Chloromycetin

Twenty-five strains of *Brucella*, including 14 strains of *Br. abortus*, 10 strains of *Br. melitensis*, and one strain of *Br. suis*, were tested for sensitivity to chloromycetin (lots No. Rx X3146 and

Repeated Exposure of *Brucella Abortus* to Decreasing Concentrations of Aureomycin

FIG. 5

Repeated Exposure of Strains of *Brucella* to Chloromycetin

FIG. 6

120021). The method used was that described for the determination of the sensitivity of *Brucella* to aureomycin. The concentration of chloromycetin required to inhibit the multiplication of the strains of *Brucella* tested varied from 1.56 to 6.25 $\mu\text{g. per ml.}$, while the concentration required to kill the organisms was from 15.6 to 125 $\mu\text{g. per ml.}$ (see Tables XVI and XVII).

The Action of Chloromycetin on *Brucella*

The method used to study the action of chloromycetin on *Brucella* was similar to that described

for streptomycin. The concentrations of chloromycetin used were 5.0, 20, and 100 $\mu\text{g. per ml.}$ The tests revealed that there was no evidence of multiplication of *Br. abortus* when exposed to chloromycetin. Viable organisms could be recovered after 48 hours from the chloromycetin-broth mixture containing 5 $\mu\text{g. per ml.}$ for five days, from the mixture containing 20 $\mu\text{g. per ml.}$ for three days, and from the tube containing 100 $\mu\text{g. per ml.}$ for two days. The results with strains of *Br. melitensis* and *Br. suis* varied from

cessful. The methods used included the exposure of a large bacterial population to concentrations of 10, 50 and 100 μg . of chloromycetin per ml., as described for streptomycin, and the repeated exposure of four strains of *Brucella* to increasing concentrations of chloromycetin (see Figure 6).

IV. OTHER ANTIBIOTICS

Eight strains of *Br. abortus* and one strain of *Br. suis* were tested for sensitivity to amorphous penicillin and to crystalline penicillin G. The broth dilution method was used. The concentration of amorphous penicillin required to prevent the multiplication of *Brucella* was found to vary from 5 to 31 units per ml., while the concentration required to sterilize the cultures was from 16 to 62 units per ml. The concentration of crystalline penicillin G inhibiting growth varied from 1.0 to 62 units per ml., whereas the sterilizing concentration varied from 12.5 to 250 units per ml.

The sensitivity of six strains of *Br. melitensis* to bacitracin was determined. Concentrations greater than 10 units per ml. were required to prevent multiplication of the bacteria. Two strains of *Br. abortus*, one of *Br. melitensis*, and one of *Br. suis* were tested for sensitivity to the antibiotic Q-19 (Research No. 8836-1). The concentration which inhibited growth of *Br. abortus* was 62.3 units per ml., though concentrations greater than 125 units per ml. were required to prevent the growth of the strains of *Br. melitensis* and *Br. suis*.

DISCUSSION

No naturally occurring strains of *Brucella* resistant to streptomycin, dihydrostreptomycin, aureomycin, or chloromycetin were found. On a weight basis, aureomycin was the most active agent against *Brucella*, streptomycin and dihydrostreptomycin were slightly less active, and chloromycetin was the least active antibrucella agent. There was very little strain or species variation in the sensitivity of *Brucella* to streptomycin, dihydrostreptomycin, or aureomycin, but there was considerable variation from strain to strain in chloromycetin sensitivity.

Streptomycin and dihydrostreptomycin were rapidly bactericidal in their action against *Brucella*. Aureomycin and chloromycetin, on the

other hand, acted primarily by preventing the multiplication of the bacteria, and concentrations much higher than have been reported in the blood were necessary to kill *Brucella*.

Strains of *Brucella* resistant to streptomycin and dihydrostreptomycin could be readily produced *in vitro* by culturing a large bacterial population in the presence of the antibiotics, suppressing the sensitive organisms in the population and allowing the normally present resistant variants to multiply. Similar attempts to produce strains resistant to aureomycin and chloromycetin were unsuccessful. Attempts to adapt strains of *Brucella* to growth in the presence of high concentrations of aureomycin and chloromycetin by repeated exposure of the organisms to the antibiotics were also largely unsuccessful. One would be tempted to predict from these results that the development of resistance of *Brucella* in human infections to streptomycin and dihydrostreptomycin might occur rapidly and frequently, but resistance to aureomycin and chloromycetin would occur infrequently and progress very slowly.

The problem of the development of resistance of *Brucella* as a cause of failure in the therapy of human infections was investigated by determining the sensitivity of strains of *Brucella* recovered from patients after therapy. Of approximately 26 patients with bacteriologic proved brucellosis due to *Br. abortus* treated at the University of Minnesota Hospitals, there have been six relapses following combined sulfadiazine and streptomycin therapy, while approximately 30 of 65 patients treated in Mexico with infections due to *Br. melitensis* subsequently had proven bacteremia. There were two relapses out of 12 patients with infections due to *Br. abortus* following aureomycin therapy, while *Brucella* were recovered after treatment from five out of 26 patients with infections due to *Br. melitensis*. The clinical use of chloromycetin in brucellosis is now being studied.

Of the 13 cultures of *Brucella* isolated after combined streptomycin and sulfadiazine therapy, one strain of *Br. melitensis* showed increased resistance to streptomycin. Another strain of *Br. abortus*, recovered after therapy with streptomycin alone, had marked resistance to the drug. There was no evidence of an increase in the normally present streptomycin-resistant variants in the strains which failed to respond to therapy.

Three strains of *Br. melitensis* and one strain of *Br. abortus*, cultured from human subjects, after aureomycin therapy, showed no changes in sensitivity to aureomycin.

One may conclude from these studies that the relapse of brucellosis following combined streptomycin and sulfadiazine or aureomycin therapy is rarely due to a change in the sensitivity of the bacteria to streptomycin or aureomycin. The evidence suggests that the strains cultured following therapy, with the exception of the two streptomycin-resistant strains, are identical to the strains isolated from the same patients before therapy. The most likely explanation for these therapeutic failures is that the antibiotics do not actually come into direct contact with all the *Brucella* harbored by the host within tissue cells, within granulomata present in the reticuloendothelial system, or within other walled-off foci (12). These and other possibilities are now being investigated.

SUMMARY

1. Strains of *Br. abortus*, *Br. suis*, and *Br. melitensis*, isolated from patients before antibiotic therapy, were sensitive *in vitro* to concentrations of streptomycin and dihydrostreptomycin of 1.0 to 2.5 $\mu\text{g. per ml.}$, to aureomycin in concentrations of 0.6 to 1.5 $\mu\text{g. per ml.}$, and to concentrations of chloromycetin of 1.56 to 6.25 $\mu\text{g. per ml.}$

2. The action of streptomycin against *Brucella* was bactericidal, while aureomycin and chloromycetin were bacteriostatic in their action.

3. Resistance of *Brucella* to streptomycin and dihydrostreptomycin could be developed readily *in vitro*, but increased resistance to aureomycin and chloromycetin was not demonstrated.

4. The study of 13 strains of *Brucella* isolated after combined streptomycin and sulfadiazine therapy revealed no change in their sensitivity to streptomycin with the exception of one strain of *Br. melitensis*, which increased in resistance from 2.5

to 50,000 $\mu\text{g. of streptomycin per ml.}$ One strain of *Br. abortus* isolated after a course of streptomycin alone increased in resistance from 1.0 to 10,000 $\mu\text{g. of streptomycin per ml.}$ Three strains of *Br. melitensis* and one strain of *Br. abortus* recovered from patients after aureomycin therapy showed no change in sensitivity to aureomycin.

ANTIGENIC AND ENZYME SYSTEM CHANGES IN BETA HEMOLYTIC STREPTOCOCCI RESISTANT TO PENICILLIN, STREPTOMYCIN, BACITRACIN AND AUREOMYCIN^{1, 2, 3, 4}

By HORACE M. GEZON AND DORCAS M. FASAN

(From the Department of Pediatrics, University of Chicago)

Previous reports from this laboratory (1, 2) have presented preliminary data suggesting that there are antigenic and enzyme system changes in beta hemolytic streptococci resistant to penicillin and streptomycin. These data were all qualitative and were unconfirmed by quantitative methods.

The present study is a continuation of this work. The same strains of group A and C streptococci were made resistant separately to bacitracin and aureomycin. Representative members of each group, resistant to all four antibiotics, were studied for alterations in: 1) streptolysin S; 2) streptokinase; 3) proteinase; 4) ribonuclease activity.

That such variations might be expected was first suggested by the observation that reversible changes in the hemolytic behavior of streptococci from beta to alpha or gamma type of hemolysis occurred when the organisms were growing on maximal concentrations of either penicillin or streptomycin.

MATERIALS AND METHODS

Strains of Streptococci

Seven group A strains and three group C strains isolated in 1946-1947 from throats of patients with acute upper respiratory infections were employed throughout the study. The strain designations for the group A or-

ganisms were: S₁, S₂, S₃, S₄, S₅, S₆, and U₇; and, for the group C strains, U₁, U₂, and U₃.

Development of Resistance

The method employed for inducing penicillin and streptomycin resistance has been described (1, 2). A similar technique was used for inducing bacitracin and aureomycin resistance. Briefly, this consisted of daily transfer of organisms from a blood agar plate containing the maximal quantity of antibiotic that would permit growth to a new series of plates containing graded amounts of antibiotic. For the streptomycin, bacitracin, and aureomycin series a total of 40 such transfers were made, and for the penicillin series 60 transfers.

Streptolysin S Production

The method described by Todd (3) was employed for all tests of streptolysin S production. Thirty ml Todd-Hewitt medium containing 20% normal horse serum inactivated at 56° C. for 30 minutes were inoculated with 1 ml of an 18 hour streptococcal broth culture in Todd-Hewitt medium prepared with 2% Pfanstiehl peptone. After incubation at 37° C. for 12 hours, the cultures were thoroughly chilled in an ice water bath, centrifuged at 3,000 rpm for 20 minutes and the supernate filtered through Sela candles (No. 02 porosity with a maximum pore size of 0.85 micron). Only cultures of resistant strains with densities that matched that of the control strain, i.e., the parent organism transferred 40 times on plain blood agar medium, were employed. The densities were determined in a Coleman Junior Spectrophotometer. Filtrate dilutions ranging from 1:4 to 1:200 were prepared in cold physiological saline so that, after the addition of 0.5 ml of a 5% suspension of fresh triple-washed rabbit RBC's, the final volume was 2.0 ml. The hemolytic end point was considered to be the dilution which showed approximately 50% hemolysis after incubation for 30 minutes in a 37° C. water bath. The lysin then was titrated against anti-streptolysin S rabbit serum (4).

Streptokinase Activity

The method employed for determining the streptokinase activity of the supernate of the broth culture was essentially that described by Kaplan (5). The fibrinogen⁵

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

² This investigation was supported (in part) by a research grant from the Division of Research Grants and Fellowships of the National Institutes of Health, U. S. Public Health Service, and by a research grant from The Abbott Laboratories.

³ Aureomycin was supplied by the Lederle Laboratories Division, American Cyanamid Co., through the Antibiotics Study Section of the National Institutes of Health.

⁴ Bacitracin was supplied by the Commercial Solvents Corporation, through the Antibiotics Study Section of the National Institutes of Health, and by Dr. Frank L. Melroy of Columbia University.

⁵ The fibrinogen employed was Fraction I of the plasma proteins prepared by the Department of Physical Chemistry, Harvard Medical School, Boston, Mass., from blood collected by the American Red Cross, and generously supplied by Dr. Edwin J. Cohn and Dr. John T. Edsall.

was used in a concentration of 600 mg dissolved in 100 ml phosphate-buffered physiological saline at pH 7.4. Purified human thrombin was prepared so that each ml of buffered saline contained approximately 3 units. The fibrinolytic titer was expressed as the reciprocal of the dilution in which there was complete dissolution of the clot after incubation in a water bath for one hour at 37° C.

Proteinase Activity

The streptococcal proteinase activity in broth cultures was measured by the method described by Elliott and Dole (6). Briefly, this consisted of observing the rapidity and degree of coagulation of a skimmed milk-thioglycollate substrate by sterile broth culture filtrates. Twenty-four hour cultures of streptococci in Todd-Hewitt broth containing 2% Pfanstiehl peptone were filtered through Selas candles (No. 02 porosity). Maintaining sterility, two-fold dilutions of filtrate were made in phosphate buffer pH 7.0. The milk-thioglycollate substrate was added with an automatic pipette, and the mixture was incubated at 37° in a water bath. The test was read at one, three, five, and nine hours and the activity expressed as the reciprocal of the dilution showing coagulation at nine hours.

Ribonuclease Activity

The ribonuclease activity of culture supernates was determined by the turbidimetric method described by McCarty (7). The substrate, yeast ribonucleic acid, was purified by the method of Kunitz (8). The optical densities were determined on a Coleman Junior Spectrophotometer at a wave length of 425 mμ, at five minute intervals over a 30 minute period.

RESULTS

The group A strains, in general, developed little resistance to penicillin and aureomycin, and

* Control organism is the parent strain after 40 transfers on plain blood agar.

† Penicillin-resistant organism is one that has been transferred 60 times on medium containing increasing concentrations of penicillin.

‡ Streptomycin-, bacitracin-, and aureomycin-resistant organisms are those that have been transferred 40 times on media containing increasing concentrations of each antibiotic.

considerable resistance to streptomycin and bacitracin. The group C strains showed similar group behavior to each antibiotic. The results are given in Table I.

The rate at which a given strain of beta hemolytic streptococcus acquired resistance to an antibiotic was not uniform in the case of penicillin, streptomycin, bacitracin, and aureomycin. For example, strain S₄ after 60 serial transfers on penicillin medium showed no change in sensitivity, after 40 serial transfers on aureomycin medium only slight resistance, but considerable resistance to streptomycin and bacitracin after 40 subcultivations on media containing these antibiotics.

Streptolysin S production was reduced for each group A organism after acquiring either penicillin or streptomycin resistance. The same strains after acquiring bacitracin or aureomycin resistance maintained the same level of hemolysin production as the control strain. The group C organisms behaved somewhat differently in their production of streptolysin S. The three penicillin-resistant and three bacitracin-resistant organisms all produced less hemolysis than the control strains. The streptomycin-resistant and aureomycin-resistant strains showed little if any change. The results are given in Table II.

derstanding of the mechanism of action of acquired antibiotic resistance. Further, it is not known why penicillin and streptomycin resistance appears to alter the behavior of streptococci to a much greater extent than does either bacitracin or aureomycin resistance. The degree of resistance for streptomycin and bacitracin and that for penicillin and aureomycin are comparable.

The variables of medium, time, temperature and amount of growth so far have been eliminated as the probable explanation for the reduced enzymatic production by the resistant variants. Each series of organisms was grown for the same period of time, at the same temperature, in a single lot of medium and on the same day. In every instance, the density of the resistant variants was matched turbidimetrically with that of the parent and control organisms.

The possibility exists, of course, that during the numerous serial transfers another strain of streptococcus was introduced through air-borne contamination or through a change in serial order of several strains on a single plate. This is partially answered by the fact that all of the resistant variants for all four antibiotics were of the same group as the parent organism. Strains that were ungroupable after acquired penicillin resistance have not been included in this study. Final proof will come from typing the parent and resistant strains. This is now in progress.

PATTERNS OF BACTERIAL RESISTANCE TO PENICILLIN, AUREOMYCIN, AND STREPTOMYCIN¹

By M. DEMEREC

(From the Department of Genetics, Carnegie Institution of Washington, Cold Spring Harbor, N. Y.)

During the last few years genetic research with bacteria has made significant progress, and ample evidence has accumulated to show that the hereditary mechanism operating in bacteria may be similar to that in higher organisms. It has been demonstrated that hereditary changes, comparable to mutations, occur in bacteria, and that these cover a range of types similar to those found in fungi, where genetic analysis is possible (1). Furthermore, an association resembling linkage in higher organisms has been observed in bacteria (2).

Experimental evidence indicates that changes in bacteria from sensitivity to resistance to penicillin and streptomycin originate as mutations, and that these antibiotics act only as selective agents which eliminate the sensitive bacteria and thus allow the resistant mutants, which are always present in any large population, to multiply (3). Experiments have revealed that the development of high resistance follows a definite pattern, which appears to be characteristic for each antibiotic and which is not determined by the bacteria involved. Detailed analyses of the pattern of streptomycin resistance have been made by me with *Escherichia coli* and *Staphylococcus aureus*, and by Dr. V. Bryson (unpublished) with *Mycobacterium ranae*. This work has revealed a remarkable similarity of behavior in these species of bacteria. Quantitative studies of penicillin resistance have been made only with *Staphylococcus aureus* (4, 5), but the results of other investigators, who have studied various phases of the action of penicillin with a wide variety of species, do not suggest that the pattern of resistance to penicillin is different in other bacteria from that analyzed with *Staphylococcus*.

At present two patterns of resistance have been established, the penicillin pattern and the streptomycin pattern. A "stepwise" development of re-

sistance is common to both, but they differ significantly in the manner in which high-level resistance is arrived at. In the case of penicillin, the first-step resistant mutants are very uniform in their degree of resistance, which is only slightly higher than that of the original strain. Additional mutations occurring in such first-step mutants result in bacteria possessing a higher (second-step) degree of resistance, and in a similar manner third-step and still higher resistance develops. Always the variation in degree of resistance among mutants of the same step is slight. This uniformity constitutes the most striking feature of the penicillin pattern; and it explains the stepwise increase in resistance. Because a significant degree of resistance can be attained only by additional mutation in an already mutant bacterium, at least two mutations in the same individual are required to bring it about. Since the mutation rate is low, however—about 1×10^{-8} per bacterium per generation—the chances for simultaneous occurrence of such double mutations are extremely low (1×10^{-16} , or practically nil), so that a large number of first-step resistant bacteria must first be present in order that a second-step mutant may occur. In other words, higher resistance may be attained only in successive steps, and no step may be skipped in this process.

The streptomycin pattern of resistance differs from the penicillin pattern in that the variation between first-step mutants is very great. They range from individuals only slightly more resistant than the original bacteria to those having complete resistance to streptomycin. Thus, although higher resistance may be attained in successive steps, as with penicillin, it may also arise in a first-step mutant.

I have attempted to analyze the resistance pattern for aureomycin, but this work has been complicated by the mode of action of that antibiotic on *Escherichia coli*, the organism used for the experiments. It was found that aureomycin, in addition to killing some of the bacteria, suppresses

30	0	0	0	0	0.7

division in the survivors. Since the aureomycin loses some of its potency during an experiment, these suppressed bacteria begin to divide again whenever the concentration of antibiotic on the plate is lowered to a certain point (Table I). If a large number of bacteria is plated, some will begin to grow earlier than others. In the anticipation that these might be more resistant to aureomycin, they were used to establish strains, which were tested for resistance; and from these a further selection of early growers was made. In this way strains that appeared to be more resistant to aureomycin were obtained. One such strain, obtained through five selections, when plated in broth-agar containing 10 μg of aureomycin per ml, gave 50 per cent survival, with colonies appearing after 48 hours of incubation. Under similar conditions, the original strain gave 29 per cent survival, the colonies appearing only after 120 hours of incubation.

These results show definitely that the pattern of aureomycin resistance is different from that of streptomycin resistance, in that highly resistant mutants do not appear in one step. It may be similar to the penicillin resistance pattern, but analysis to determine this has not been carried through because of complications introduced into the experiments by the loss of potency of aureomycin.

The genetic mechanism responsible for both the penicillin and the streptomycin resistance patterns may be explained by the assumption that several genes govern the reactions that determine sensitivity or resistance, and that the set of genes affecting penicillin resistance is different from the set of

genes affecting streptomycin resistance. If any one of these genes should mutate, the bacterium in which such a mutation occurs and the strain developed from that bacterium will be more resistant to the respective antibiotic than was the original parent strain. Such a strain is what we have called a "first-step resistant strain."

The fact that first-step penicillin-resistant strains are fairly uniform in degree of resistance is consistent with the assumption that all genes affecting resistance to penicillin have a similar potency, so that the effect of mutation is the same regardless of which of the genes happens to mutate. According to this hypothesis, there is still present in a first-step resistant strain a number of unmutated genes that affect resistance. Mutation of any of these produces a second-step resistant strain, which possesses a higher degree of resistance than the first-step strain. Similarly, by mutation of another gene in a second-step resistant strain, a still higher degree of resistance is attained, characteristic of the third-step resistant strain; and by further repetition of the process a very high degree of resistance may be reached.

The observed behavior of resistance to streptomycin also can be explained by assuming the existence of several genes determining such resistance. Unlike the genes for penicillin resistance, however, these differ greatly from one another in potency. If a gene of low potency mutates, the first-step resistant strain will have a low degree of resistance, but if mutation occurs in a highly potent gene, the first-step resistant strain will be highly resistant. Consequently, considerable variation in degree of resistance is to be expected between first-step strains; and for the same reason a highly resistant strain may be obtained either in one step, by selection of a highly resistant first-step mutant, or in several steps, by selection of mutants of low resistance values.

The assumption that several genes are responsible for resistance is not unusual; a similar assumption, involving the presence of about 20 genes, has already been made to explain the complex situation observed in a study of resistance of *E. coli* to several bacteriophages (6). Also, experiments now under way in my laboratory indicate that several genes are involved in changes of *E. coli* from streptomycin sensitivity to strepto-

mycin resistance and dependence, as well as in reversions from dependence to sensitivity.

THE PARTIAL PURIFICATION AND PROPERTIES OF ANTIBIOTIC SUBSTANCES FROM THE SWEET POTATO PLANT (*IPOMOEA BATATAS*)^{1, 2}

By B. H. BRUCKNER, HAZEL H. MCKAY, P. S. SCHAFFER,
AND THOMAS D. FONTAINE

(From the Bureau of Agricultural and Industrial Chemistry, Agricultural Research Center,
Beltsville, Maryland)

The dramatic chemical and therapeutic successes of certain antibiotics, notably the penicillins and streptomycin from *Penicillium* and *Actinomyces* molds, have spurred the search among other microorganisms and, more recently, among angiosperms for additional substances possessing antibacterial and antifungal properties.

Within the past few years it has been repeatedly shown by many investigators that some plant juices and extracts of dried whole plants and plant parts contain various kinds and intensities of antibacterial and antifungal activity (1-8).

In connection with investigations in this laboratory it has been previously reported (7) that the autoclaved expressed juice of the sweet potato plant (*Ipomoea batatas*) inhibited cultures of several plant-wilt producing *Fusaria*. The present investigations have confirmed and elaborated upon this early observation.

It is the purpose of this paper to present a procedure for obtaining crude and partially purified preparations of antibiotic substances from the sweet potato plant, to discuss some of the chemical, physical, bacteriological, and mycological properties of the various active fractions, and to present some of the speculative implications of this work in connection with the problems associated with some human, and possibly animal, diseases.

To date, no pure antibacterial or antifungal compound has been isolated. Since the crude extracts and some of the partially purified fractions were considered relatively impure and were found to contain both inhibitory and some stimulatory material, it was not deemed advisable, as yet, to

set up an arbitrary unit of activity. It will thus be appreciated that the results reported here have only qualitative significance and that the interpretations of the results must be regarded as tentative.

EXPERIMENTAL

Two varieties³ of sweet potato plants were used throughout this work. One variety was *Fusarium*-wilt-resistant (designated *Res.*), whereas the other variety was *Fusarium*-wilt-susceptible (designated *Susc.*).

Using the familiar disc and cup-plate assay method with slight modifications to be described, the test microorganisms listed in Table I were employed in this work.

Method of assay

A. Into individual, sterile, 90-mm. Petri dishes were poured base layers of 20 ml. of agar as follows:

1. Nutrient agar—for all bacteria except *Mycobacterium phlei*
2. Glycerol agar—for *M. phlei*
3. Czapek-dextrose agar (3) for the *Fol.* and *Fob.*

B. The inocula were prepared and introduced onto the plates as follows:

1. For all bacteria except *M. phlei*:

Two-tenths of a milliliter of a 24-hr. nutrient broth culture was added to 5 ml. of warm (42° C) nutrient agar. This seed layer was then evenly poured over the agar surface of a prepared Petri dish. The agar was allowed to harden, and the covered plate was then incubated for one-half hour at 37° C before "spotting" or the addition of test solution.

2. For *M. phlei*:

Five milliliters of an homogenized and filtered four-day-old culture were added to 50 ml. of warm (42° C) glycerol agar. Four milliliters of this suspension was evenly flooded over the agar surface of a Petri dish. The covered dish was then incubated for one hour at 37° C before "spotting."

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

² Report of a study made under the Research and Marketing Act of 1946.

³ *Ipomoea batatas*. No. 153655, *Fusarium*-wilt-resistant variety, and Puerto Rico Unit 1, *Fusarium*-wilt-susceptible variety. Both varieties were grown at Beltsville, Maryland, and obtained from the Bureau of Plant Industry, Soils, and Agricultural Engineering.

Wellman, formerly Bureau of Plant Industry, Soils, and Agricultural Engineering, Beltsville, Maryland.

3. For *Fol.* and *Fob.*:

Six milliliters of sterile distilled water were used to wash down a four-day-old potato-dextrose slant of the organism. This aqueous suspension of spores was filtered through a thin, sterile, cotton plug to remove bits of the mycelium which would tend to give rise to irregular growth, if plated. One and three-tenths ml. of this filtrate were added to 100 ml. of liquid Czapek-agar (42° C), and 4 ml. of the resulting suspension were used to flood the prepared plate evenly. After hardening of the agar, the covered plate was incubated for 24 hours at 28° C before the addition of the test solutions.

The technique of "spotting" consisted of saturating, by imbibition, a standard filter-paper assay disc (S & S 740-E) with the test solution and immediately placing the disc on the inoculated surface of the prepared Petri dish. If the antibiotic was dissolved solely in an organic solvent, the filter-paper assay disc was saturated and placed in a vacuum desiccator until the solvent had evaporated. The dried disc was then saturated with water and immediately placed on the inoculated surface. The covered dish was then inverted and incubated under the same optimum conditions for the growth of the organism. Biological activity was determined by the presence or absence, and the relative sizes, of zones of inhibition or stimulation.

Preliminary survey of sweet potato plants

Direct hot and cold aqueous extractions of the dried and ground whole Res. sweet potato plant resulted in

solutions which generally stimulated the growth of the characteristic test microorganisms, *Fol.*, *Fob.*, *Escherichia coli*, and, to a slighter degree, *Staphylococcus aureus*. No effect was noticed with *M. phlei*. Similar results were noted for aqueous extracts of Res. tubers, leaves, stems, and Susc. tubers and stems. The water extracts of the Susc. leaves and of the roots, as well as the water-insoluble extraction residues of all plant parts except Susc. tubers, very slightly inhibited *Fob.* Direct aqueous extractions were abandoned as being unsatisfactory.

When portions of dried and ground Res. and Susc. sweet potato plant parts were individually extracted with methanol, the extract reduced to dryness by removal of the methanol, and the resulting residue taken up in water, the aqueous solutions thus produced, in marked contrast with the direct aqueous extracts, inhibited cultures of microorganisms previously unaffected or largely stimulated. Only the extracts of Susc. stems inhibited *M. phlei*. In almost all cases stimulation of some microorganisms was apparent, concurrently with concentric zones of inhibition.

Of the various plant parts extracted and assayed, the leaves and stems of both the plant-wilt-resistant and the susceptible varieties seemed to contain at least as much, if not more, inhibitory material than did the roots and tubers. Extracts of Susc. stems appeared to be the most active of all.

Procedure for obtaining crude active extracts

Weighed samples of dried and ground Susc. sweet potato stems were extracted with methanol for eight hours in a Soxhlet extraction apparatus. The dark green methanolic extracts were then concentrated to dryness *in vacuo*, and the residues were thoroughly extracted, portionwise, with sufficient warm distilled water to make the final volumes of clear, reddish-brown aqueous extract

All the organisms listed were not used against all 13 preparations of each concentrate.

† Dilutions were made such that no more than three drops of organic solvent were added to each 10 ml. of agar on any assay plate.

represent 1 gram of original stem material per ml. The aqueous solutions thus prepared were considered "concentrates" and designated "Aq.-Conc." They were found to contain most of the antibacterial activity. The non-water-soluble residues were taken up in minimal amounts of methanol and designated "MeOH-post-Aq.Conc." The latter methanolic solutions, so prepared, contained most of the antifungal activity.

The approximate average assay results of 13 separate preparations of Aq.-Conc. and MeOH-post-Aq.Conc. are summarized in Table II.

Partial purification of active concentrates

Measured weights and volumes of the clear, reddish-brown aqueous concentrate, Aq.-Conc., were stirred batchwise for 15 min. at 25° C with from 2.0% to 2.5% (by weight) of activated carbon (Darco G-60) ⁴ while the pH of the solution was controlled in the range of 4.0 to 4.5 by the dropwise addition of 1 *N* hydrochloric acid solution. The carbon was filtered and washed with several small portions of distilled water, and the washings were added to the deep orange-brown filtrate (effluent). The carbon cake was then transferred to a beaker and to it was added a volume of distilled water—equal to that of the original sample of Aq.-Conc. used. The mixture was again stirred for 15 min. while the pH of the solution was adjusted and controlled at from 7.0 to 7.5 by the dropwise addition of 1 *N* ammonium hydroxide solution.

The carbon was then filtered from the solution, washed with several small portions of distilled water, and discarded. The washings were added to the sparkling, clear, pale-yellow eluate.

RESULTS

The average assay results obtained from three separate batchwise adsorption-elution runs are summarized in Table III.

These results seem to indicate that the water-soluble material that stimulates fungi may be separated from the materials that inhibit bacteria. The material inhibitory toward Gram-positive bacteria appeared to be concentrated in the neutral to slightly basic eluate.

Columnar adsorption using an intimate mixture of equal parts of activated carbon (Darco G-60) and Kieselguhr (Hyflo Super-Cel) resulted in irreversible adsorption of most of the active material in the original concentrates. No significant quantity of active material could be eluted, at reasonable pH values, with water, methanol, or various water-methanol mixtures. Percolation of

active concentrates through Kieselguhr (Hyflo Super-Cel) filter beds containing no carbon, likewise resulted in irreversible adsorption and consequent loss of activity.

The use of chromatographic column containing activated carbon (Darco G-60) with no siliceous filler produced indeterminate results not inconsistent with those in Table III. However, these attempts presented such mechanical difficulties that the method was abandoned. A search is now being conducted for a physically and chemically suitable and non-adsorbent filler for columnar use with finely divided carbon.

Preliminary work with synthetic ion-exchange resins, such as the "Amberlites," has been started. As yet, insufficient data have been accumulated to warrant drawing any general conclusions other than that they offer some promise for purification and concentration of the active materials.

Some properties of active preparations

The control of pH to within rather narrow limits appeared to be a critical factor for adsorption and elution of antibacterial substances. Except at the optimum pH values, an overall distribution of non-selective inhibitory and stimulatory material occurred. This was accompanied by some loss of total activity. All the active material was found to be soluble in polar, and insoluble in non-polar, solvents. The antifungal material appeared to be very soluble in methanol but not appreciably water-soluble, whereas all the antibacterial and all the stimulatory material appeared to be very soluble in water.

Samples of active preparations seemed to retain their activity after being heated for as long

⁴ The mention of this and other commercial products does not imply that they are endorsed or recommended by the Department of Agriculture over others of a similar nature not mentioned.

as eight hours at 100° C. Samples refrigerated for one week at 4° C showed no perceptible diminution of activity. The results of several investigations of serial dilutions on agar slants, made with different preparations of Aq.-Conc. against *M. phlei*, demonstrated that dilutions as low as 0.05 ml. Aq.-Conc. per ml. of total solution completely inhibited the organism. This inhibition was entirely retained after 10 days. The inhibitory material was considered bactericidal to *M. phlei*, in the aforementioned concentration, since it was found impossible to initiate growth of the organism upon transfer of the attenuated culture to a fresh slant.

DISCUSSION AND CONCLUSIONS

Crude extracts of sweet potato plant parts contained a conglomerate mixture of non-selective inhibitory and stimulatory activity. Since it has been found possible to separate, from crude extracts, individual aqueous and methanolic fractions showing, respectively, the predominate bacterial activity and the major portion of antifungal activity (Table II), and since it has been further found possible to obtain fractions of the aqueous concentrate, Aq.-Conc., which exhibit selective inhibition to Gram-positive microorganisms (Table III), it has been postulated that at least two discrete inhibitory materials and one stimulatory material may be present in the total crude concentrates.

Although no sweeping conclusions can be drawn at this time, the method successfully employed for the partial purification of the aqueous concentrates indicated that the antibiotic factor or factors responsible for the activity against Gram-positive microorganisms may be polar in nature. If the inhibitory effect against Gram-positive organisms resulted from the action of an individual substance, then, as was indicated by the results of serial dilution investigations with *M. phlei*, this substance may be a bactericide in relatively low concentrations.

It is fully appreciated by the authors that the present investigations were largely exploratory in nature and that the results reported represent work done on crude extracts and partially purified fractions. However, the partial isolation of active material selectively inhibitory, *in vitro*, to Gram-

positive microorganisms, particularly *M. phlei*, encourages speculation concerning the possible therapeutic applicability of this material in the treatment of some human, and possibly animal, mycobacterial infections. It is further realized that before any thought of possible therapeutic use of this active material can be seriously entertained, investigations in addition to those now in progress must demonstrate satisfactory and desirable kinds and degrees of activity and potency *in vivo*, stability under various conditions, and, among other properties, either no toxicity or sufficiently low toxicity to render feasible any administration.

SUMMARY

1. Aqueous and methanolic extracts of dried whole sweet potato plants and dried and ground plant parts were found, by the familiar disc and cup plate assay method, to contain both antibiotic and stimulatory activity when tested against certain Gram-negative and Gram-positive bacteria (including one acid-fast form) and two forms of plant-wilt fungi.

2. Of the plant parts from wilt-resistant and wilt-susceptible varieties that were extracted and assayed, the stems of the wilt-susceptible variety appeared to be the most desirable source of antibiotic substances.

3. By use of batchwise and columnar adsorption and elution techniques, it was possible to separate partially the antifungal from the antibacterial activity and to prepare partially purified concentrates exhibiting selective inhibitory, and possibly bactericidal, activity against Gram-positive microorganisms.

4. Preliminary evidence is cited for postulating the existence of at least three discrete biologically active materials in the sweet potato plant.

5. Some of the chemical, physical, bacteriological, and mycological properties of the active solutions are discussed.

6. Preliminary antibacterial and antifungal spectra of the various active extracts and fractions are presented.

ACKNOWLEDGMENT

The assistance of Mrs. Barbara Black in conducting antibiotic assays, and of Mr. Francis Gutz for the prep-

aration of some sweet potato extracts, is greatly appreciated.

THE PARTIAL PURIFICATION AND PROPERTIES OF ANTIBIOTIC SUBSTANCES FROM THE BANANA (*MUSA SAPIENTUM*)^{1,2}

By WILLIAM E. SCOTT, HAZEL H. MCKAY, P. S. SCHAFER,
AND THOMAS D. FONTAINE

(From the Bureau of Agricultural and Industrial Chemistry, Agricultural Research Center,
Beltsville, Maryland)

Recent investigations have shown that extracts of higher plants contain substances which inhibit the growth of bacteria and fungi (1). In a preliminary survey conducted by this laboratory, approximately 40% of the extracts from the 80 plants tested exhibited either antibacterial or antifungal activity or both. Among the plants tested was the banana. Bananas have been used clinically for dietary purposes and for some intestinal disorders (2), but their beneficial effect has never been attributed to the presence of antibiotic substances. The banana skin has been referred to as nature's bacteria-proof wrapper and investigations have shown that when bananas were immersed in fluids containing cultures of known organisms there was no evidence of a penetration into the interior (3).

The purpose of this paper is to present the partial antibiotic spectrum of extracts obtained from the pulp and skins of green, naturally ripened, and ethylene-ripened bananas, and from banana leaves and petioles, and to describe the partial purification of these antibiotic substances.

EXPERIMENTAL

Preparation of extracts

Fresh undried plant material was extracted with water. Plant material previously dried at 85° C in a forced-draft oven and ground to pass a medium Wiley mill screen was extracted with methanol or petroleum ether (b.p. 35–60° C). Aqueous, methanol, and petroleum-ether extracts were concentrated until each milliliter of solution was equivalent to 1 gm. of the plant material. In some experiments the organic-solvent extracts were evaporated to dryness and sufficient water to make each milliliter of solution equivalent to 1 gm. of original plant material was then added to the residues. Frequently, not all of the substance dissolved by organic solvent was

soluble in water. In these cases the water-soluble portion was removed, and the water-insoluble portion was tested separately. The pH of all aqueous solutions was determined and then adjusted to 6–7 for assay, although no appreciable difference in the size of inhibition zones was noted when the aqueous solutions were not adjusted from their normal pH of 4.0 to 5.5.

Method of assay

Sterile, 90 mm. petri dishes, containing 20 ml. of solidified agar media, were warmed to 45° C and flooded with 4 ml. of agar, seeded with bacterial cells or fungus spores. In the cylinder cup-plate method the plant extracts were pipetted into the cups which had been placed on the inoculated agar, and in the paper disc method the discs were immersed in the plant extract long enough to become saturated with the solution and then dried in a vacuum desiccator. Before they were placed on the inoculated agar the discs were moistened with distilled water. The agar plate was incubated for a fixed period of time at a temperature that was optimum for the growth of the organism. The zones of inhibition around the cups or discs were measured to obtain a relative indication of the amount of antibiotic agent in the extract. See (1) for source of organisms.

Antibiotic activity of crude extracts

Aqueous extracts of banana leaves and petioles showed no detectable antibiotic activity. The water-soluble portion of the substance extracted by methanol exhibited no appreciable antifungal activity, whereas the water-insoluble portion inhibited the growth of the fungus *Fusarium oxysporum* f. *lycopersici*.

Some antibacterial activity was detected in the methanol extracts of both plant parts. The water-soluble portion of the substance extracted from leaves by methanol inhibited *Xanthomonas translucens* f. sp. *hordei-avenae* and *Rhodococcus roseus* and partially inhibited *Sarcina lutea* and *Serratia marcescens*, whereas the same portion from the methanol extract of petioles inhibited *Staphylococcus aureus*, *S. luteo*, *Mycobacterium phlei*, and *R. roseus*.

A comparison of the antifungal and antibacterial activities of the water-soluble substance in methanol extracts of the pulp and skins of green, naturally ripened, and ethylene ripened bananas² is shown by Table I.

² The green, naturally ripened and ethylene ripened bananas were obtained from the Bureau of Plant Industry, Soils, and Agricultural Engineering, Beltsville, Maryland.

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11–12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

² Report of a study made under the Research and Marketing Act of 1946.

TABLE I

Comparison of the activities* of extracts obtained from the pulp and skins of green, naturally ripened, and ethylene-ripened bananas

Organism†	Skins			Pulp		
	Green	Naturally ripened	Ethylene-ripened	Green	Naturally ripened	Ethylene-ripened
<i>Fusarium oxysporum</i> f. <i>lycopersici</i>	29+	25+	29+	17-, 25+	28+	32.5+

* The numbers refer to the diameter of the zone in millimeters; for instance, 25+, 28- means an inhibition zone of 25 mm. and a stimulation zone of 3 mm. beyond the 25 mm. zone. +, inhibition; (+), partial inhibition; -, stimulation; (-), partial stimulation; 0 = no effect.

† See previous paper (1) for source of organisms.

RESULTS

Antifungal activity was exhibited by all six extracts. There was very little, if any, measurable antibacterial activity in either the pulp or skins of green bananas, but there was appreciable antibacterial activity in the pulp and skins of ripe bananas. In some instances the inhibition zones were surrounded by zones of stimulation. This may be due either to the carbohydrates which are present, mainly as sugars, in ripe bananas (4) or to a subminimal amount of antibiotic at the outer edge of the zone of inhibition or to a combination of both factors. The partial inhibition zones resulting from extracts of the pulp and skins of green bananas may be explained by the fact that some of the bananas were partly ripe. It appears that the antibacterial activity of bananas is due to the formation of inhibitory compounds during ripening. Petroleum ether did not extract any of the active substance from either the pulp or the skins.

Agar slants of the water-soluble portion of a crude methanol extract of the skins indicate that the substance at a concentration of 0.25 gm. of

dried plant material per ml. of medium is fungistatic to *F. oxysporum* f. *lycopersici*, *Trichophyton mentagrophytes*, *Monosporium apiospermum* and *Blastomyces dermatitidis*.

Fractionation and partial purification

Dried skins (1,325 gm.) from ethylene-ripened and naturally ripened bananas were combined and extracted, batchwise, with 10 successive 1,500-ml. portions of hot methanol, and the combined extracts were subsequently concentrated to approximately 2 liters. When this concentrate was cooled to -20° C, some resinous material was precipitated. The supernatant methanolic solution was filtered and concentrated under reduced pressure to approximately 1,300 ml. so that each ml. of solution represented about 1.0 gm. of dried skins. This solution showed a notable increase in antifungal activity, producing an inhibition zone of 62 mm. against *F. oxysporum* f. *lycopersici*, which is more than twice the diameter of the zone produced by solutions from which the resinous material had not been separated, but it did not show any appreciable change in antibacterial activity. As-

says of ethanol solutions of the resinous material showed slight inhibitory activity toward bacteria and some stimulatory activity toward *F. oxysporum* f. *lycopersici*.

Thus far, chromatographic adsorption of the antibiotic substances in methanol extracts, and in the petroleum-ether-soluble portion of methanol extracts, by activated alumina has not proved very satisfactory. Activated carbon (Darco G-60)⁴ did not adsorb the antibiotic substances from an aqueous extract (pH 5.0) of the methanol concentrate.

Low pressure distillation of a methanol concentrate of ripe banana skins produced a small amount of liquid from which a few crystals have been obtained. During the distillation, at 2-mm. pressure, the tendency to foam was controlled by cautious heating. A few drops of distillate were collected at a pot temperature of 180–190° C, and a few additional drops as the pot temperature rose to 250° C. Both distillates were readily soluble in ethanol, but upon the addition of a few drops of water the solutions became turbid. Crystals formed in each solution when cooled in the refrigerator for a few days. At the time of writing, the crystals had not been tested for antibiotic activity, but the original solution from which the crystals separated had been found to exhibit both antifungal and antibacterial activity (Table II). The physical and chemical properties of the crystalline substance have not yet been determined.

DISCUSSION

The results show that all four parts of the banana plant tested contain some extractable antibiotic

agent(s). Since the pulp and skins of both green and ripe bananas showed antifungal activity, and the pulp and skins of only ripe bananas showed antibacterial activity, it seems likely that there are at least two separate antibiotic agents in ripe bananas. Further, the antibacterial substance appears to be a product formed during the ripening process. It is interesting to note that a vacuum-distillable substance was obtained from ripe banana skins which had both antifungal and antibacterial activity.

Adsorption on alumina and on activated charcoal produced no positive results, but these procedures have not yet been fully investigated.

The *in vitro* antifungal and antibacterial activity of the various parts of the banana plant warrants further investigation to isolate, identify and characterize the active substance or substances. Because of the *in vitro* effectiveness of these principles, toxicological investigations are now in progress.

SUMMARY

1. Extracts of banana leaves were found to be only slightly antibacterial, whereas extracts of stems inhibited the growth of two Gram-positive, one acid-fast Gram-positive, and one Gram-variable bacterium.

2. Extracts of the pulp and skins of green bananas inhibited only the fungus *F. oxysporum* f. *lycopersici*.

3. Extracts of the pulp and skins of ripe bananas effectively inhibited *F. oxysporum* f. *lycopersici*, *Escherichia coli*, *Staph. aureus*, *S. marcescens*, *M. phlei*, *Bacillus subtilis*, *S. lutea*, *R. roseus*, and *X. translucens* f. sp. *hordei-avenae*.

4. A substance distillable at low pressure effectively inhibits *F. oxysporum* f. *lycopersici*, *E. coli*, *Staph. aureus*, *S. lutea*, *M. phlei*, *Bacillus cereus*, and *X. translucens* f. sp. *hordei-avenae*.

5. The results indicate that the banana plant contains one or more substances with therapeutic possibilities provided their toxicity and *in vivo* activity are favorable.

ACKNOWLEDGMENT

The assistance of Mrs. Barbara Black in conducting antibiotic assays, and of Mr. Francis Gony for the preparation of some banana extracts, is greatly appreciated.

⁴ The mention of this and other commercial products does not imply that they are endorsed or recommended by the Department of Agriculture over others of a similar nature not mentioned.

ANTIBIOTIC STUDIES ON AN EXTRACT FROM *LEPTOTAENIA MULTIFEDA*^{1, 2, 3}

By G. A. MATSON, A. RAVVE, J. M. SUGIHARA, AND W. J. BURKE

(From the Departments of Bacteriology and Chemistry, University of Utah, and the Latter-Day Saints Hospital, Salt Lake City, Utah)

Numerous surveys (1-8) have demonstrated the wide occurrence of antibioticly active materials in higher plants. In a recent investigation Matson and Flowers (9) examined 440 plants found in Utah and neighboring states. Certain of these plants have long been used for medicinal purposes by both American Indians and white men. Among the families which appeared to contain a higher percentage of species and genera containing antibiotic substances was the *Umbelliferae* family. Matson and Flowers found in preliminary experiments that an aqueous extract of the root and leaves of *Leptotaenia multifida*, commonly known as "Indian carrot," inhibited growth of *Micrococcus aureus* and *Escherichia coli*. The root of *L. multifida* has been used by the Gosiute Indians in the form of a paste for application upon wounds, cuts or bruises where the skin was broken (10). This dressing was particularly applied in case of infection.

Some of the preliminary work of the present paper was reported by Ravve (11). At about the same time a publication by Carlson and Douglas (12) described the antibiotic activity of oil fractions obtained from the root of a related plant, *Leptotaenia dissecta*. Further work on the extraction and purification of an oil from the root of *L. multifida* and a study of its antibiotic properties is herein described.

METHODS

Extraction and purification. *L. multifida* was collected on the foothills of the Wasatch Range northeast of Salt Lake City, Utah. The plants were stored in a refrigerator

until used. Among the several methods studied for the extraction of oil from the root, the following represents a preferred procedure. The water-washed and peeled root was macerated in a meat grinder, placed in a flask and covered with ethyl acetate. After 24 to 48 hours at room temperature the mixture was filtered, and the solvent was removed under reduced pressure from the yellow filtrate. The recovered ethyl acetate was suitable for reextraction purposes. The extraction was conducted at room temperature in order to minimize any tendency toward loss of activity through polymerization. The extraction of a given batch of root was repeated three times. This procedure yielded approximately 9% of crude extract by weight of the cleaned, peeled, wet root of *L. multifida*.

The crude extract was washed 10 or more times with water. This treatment gave material which will be designated as extract purified by water washing.

A more complete purification procedure involved treatment with sodium bisulfite. The crude oil was first washed thoroughly with a dilute, aqueous solution of sodium bicarbonate and then thoroughly washed with water. To 150 ml. of a saturated solution of sodium bisulfite in 95% ethanol was added a solution of 25 ml. of oil in 150 ml. of absolute alcohol. The resulting precipitate was filtered and washed with several portions of ethanol. There was no visible evidence of unreacted oil. The bisulfite addition complex was added to a two phase mixture of 30% aqueous acetic acid and petroleum ether (b.p. 30-60° C.). The petroleum ether, containing the liberated oil, was washed 10 or more times with water and dried over anhydrous sodium sulfate. Solvent removal under reduced pressure left the regenerated oil in 50 to 60% yield based on the crude oil. The resulting product was dissolved in alcohol-free benzene and was passed through a column packed with Magnesol⁴-Celite⁵ (five to one, by weight) to remove polymerized material. Solvent removal left a light yellow oil in approximately 50% yield based on the bisulfite purified extract. Elution of the column with 200 to 1 benzene-ethanol (by volume) followed by solvent removal gave a brown viscous oil.

The use of ethylene glycol as a carrier in distillations under reduced pressures appeared to be useful if small quantities only of the oil were desired. At 60° C. and several microns pressure ethylene glycol and the oil, which were immiscible, distilled in the volume ratio of about five to one, respectively.

²This investigation was aided by a grant from the Miles Laboratories, Inc., Elkhart, Indiana.

³Presented at the Symposium on Recent Advances in Antibiotics Research, sponsored by the National Institutes of Health, Washington, D. C., April, 1949.

Agar plate assay. To 250 ml. of cooled melted agar medium was added 5 ml. of an 18 to 24 hour broth culture of the test organism. An amount of 20 ml. of the seeded agar was poured into each petri plate and allowed to harden at room temperature. A sterile filter paper disc 10 mm. in diameter was immersed in the material to be assayed. Excess liquid was allowed to drain, and the disc was placed in the center of the poured plate. Plates were observed after 18 to 24 hours incubation at 37° C. The diameter of the zone of inhibition was measured to the nearest millimeter and noted as complete or partial. The figures given are averages of three or more plates. Dilutions of the materials tested were made in sterile mineral oil, Saybolt viscosity 335-350 at 38° C. Mineral oil controls were made with each organism. Penicillin G sodium at a concentration of 10^{-2} Gram per ml. of aqueous solution was used for comparative purposes. In addition Duracillin diluted with peanut oil to contain the same number of penicillin units per ml. as the aqueous solution was employed.

Broth tube assay. To 4.5 ml. of serial dilutions of the oil in sterile mineral oil was added 0.05 ml. of a one to 100 dilution of an 18- to 24-hour broth culture of the test organism. The tubes were shaken to distribute the organisms thoroughly through the mineral oil. After one-fourth, one-half, one, eight, and 24 hours, loopfuls (diameter of loop 4 mm.) of the suspensions were withdrawn from each tube and added to sterile broth. All tubes were observed for growth 48 hours after inoculation.

Toxicity assay. The animals used were 20-Gram, male, Swiss, white mice eight to ten weeks old. All mice received one subcutaneous injection. In certain instances the oils were diluted with sterile peanut oil to facilitate injection. The crude extract was free of ethyl acetate. Sterile peanut oil was used as the control.

RESULTS

Ethyl acetate extraction of the washed and peeled macerated root of *L. multifida* provided a rapid and convenient means of obtaining a yellow, water insoluble oil in high yield.

The crude extract was tested *in vitro* for antibacterial properties against 14 representative Gram-positive and Gram-negative organisms (Table I). Complete or partial inhibition of growth was exhibited with ten organisms including all of those belonging to the Gram-positive group. In most cases in which the oil was active, it was effective at a concentration of 10^{-3} in mineral oil. At comparable concentrations (10^{-2}) penicillin and the crude oil were roughly equally effective against the organisms susceptible to both agents.

The extract purified by water washing was also evaluated in agar plate tests (Table II). On the whole and particularly at the lower concentrations, thorough washing with water appeared to have resulted in greater activity. The aqueous extracts from the washing treatments did not show any appreciable activity against Gram-positive organisms.

The effectiveness of the water-washed extract against three organisms in nutrient broth tests was also determined (Table III). These results were comparable with those obtained in agar

<i>M. tuberculosis</i> , var. <i>hominis</i>	40	40	22	15	11

plate tests in that the oil was much more active against the Gram-positive organisms.

Regeneration of the oil from the crystalline sodium bisulfite addition complex was accomplished by treatment with aqueous acetic acid. Although the reaction mixture was cooled, some polymerization appeared to have occurred as evidenced by the increased viscosity of the resulting oil. When this material in benzene solution was passed through a column packed with Magnesol-Celite (five to one, by weight), an oil with greater fluidity was obtained upon removal of solvent. The activity of this material was determined (Table IV) and found to be significantly greater than either the crude or the water-washed extract. The dark viscous oil adsorbed on the column exhibited but little activity against *M. aureus*.

The crude oil was found to be effective against both pathogenic and non-pathogenic acid-fast organisms (Table V). In all cases zones of complete inhibition were obtained at a concentration as low as 10⁻⁴ in mineral oil.

TABLE VI
Toxicity of extract toward mice

	Dose in ml.	No. of mice	Fatalities
Crude	0.025*	3	0
	0.05†	3	3
Water washed	0.30	2	0
	0.50	2	0
Bisulfite purified	0.05†	3	0
	0.18‡	3	0
Passed through column	0.18	2	0
Adsorbed on column	0.15	2	0
Peanut oil control	0.50	3	0

* Diluted to 0.05 ml. with peanut oil

† Diluted to 0.10 ml. with peanut oil

‡ Diluted to 0.27 ml. with peanut oil

Crude, water-washed, and bisulfite-purified specimens of the oil were tested for toxicity toward mice. Bisulfite-purified extract passed through Magnesol-Celite and material adsorbed on the column were also evaluated. The low toxicity of the water-washed and bisulfite-purified oils was indicated by the fact that subcutaneous injections of from 0.9 to 2.5 % of body weight of the mice did not noticeably affect their behavior (Table VI). Tolerance of the crude extract before washing with water was considerably lower.

The heat sensitivity of the crude oil was indicated by the reduction of activity against *M. aureus* and also by the increase in viscosity when the oil was maintained at 100° C. or higher for one hour (Table VII). Oil obtained by steam distillation of the crude extract at atmospheric pressure (640 mm.) likewise showed reduced activity against

TABLE VII
Effect of heat on a crude extract

Conc. in mineral oil	Activity against <i>Micrococcus aureus</i> Diameter of zone of inhibition in mm.			
	Control unheated	1 Hour at °C.		
		100	150	200
10 ⁻¹	47	40	15	27
10 ⁻²	36	19	18	11
10 ⁻³	25	15	11	n
10 ⁻⁴	21	11	n	n
10 ⁻⁵	14	n	n	n

this organism. No appreciable loss of activity against *M. aureus*, however, was noted when the crude oil was heated in ethyl acetate at 69° C. for two hours.

DISCUSSION

The fact that an antibiotically active oil can be extracted from *L. multifida* in high yield has greatly facilitated the investigation of this material since ample quantities for the desired laboratory studies were readily obtained.

While the oil was quite effective in agar plate tests against certain Gram-negative organisms such as *Vibrio comma* and *Neisseria catarrhalis*, it appeared to be much more generally active against members of the Gram-positive group. This was indicated by the complete inhibition obtained even at concentrations of 10⁻³ with all Gram-positive organisms used. These included

M. aureus, *Corynebacterium diphtheria*, *Diplococcus pneumoniae* III, *Streptococcus pyogenes*, and *Bacillus subtilis*. These tests suggest that the oil diffused through an essentially aqueous medium. A water-insoluble antibiotic of this nature might afford effective action for a comparatively long period of time *in vivo*. The oil was also effective *in vitro* against *Mycobacterium tuberculosis*, var. *hominis* and the two other acid-fast organisms tested. The results indicate the desirability of *in vivo* tests, which are in progress.

Washing the crude extract with water provided an effective means of removing material which was somewhat toxic to mice. The fact that subcutaneous injections of water-washed oil equivalent to 2.5% of the weight of the mice did not produce any deaths, or even any noticeable difference in behavior, suggested that the active material was only slightly if at all toxic to mice when administered in this way.

Heat stability tests showed that the oil underwent polymerization readily at 100 to 200° C. with a gradual loss in activity against *M. aureus*. This tendency toward polymerization upon heating complicated the purification of the oil since conventional distillation procedures even at low pressures and in the presence of antioxidants were not feasible. Distillation in the presence of immiscible liquids such as water or ethylene glycol offered a means of obtaining small quantities of distilled oil. A purification procedure involving regeneration of the oil from a sodium bisulfite addition complex, however, was found to be a convenient means of obtaining an oil of greatly enhanced antibacterial activity.

The oil, obtained by ethyl acetate extraction of the root of *L. multifida*, appeared to be quite different in certain respects from the oil fractions Carlson and Douglas (12) obtained by the steam distillation of the root of *L. dissecta*. Both of these plants belong to the *Umbelliferae* family. The yellow oil obtained from *L. dissecta* was reported to decolorize upon standing in air and to be bactericidal against *E. coli* in a short time in broth tests. This behavior was clearly in contrast with that shown by the oil from *L. multifida*, which showed no tendency toward decolorization even after several weeks in air, and which was only slightly effective against *E. coli* in broth tests and then only after long contact. Further, the active

oil obtained by Carlson and Douglas was described as being heat stable while the extract of *L. multifida* undergoes polymerization at temperatures of 100° C. or higher with a concomitant reduction in activity.

Major emphasis thus far has been placed on the extraction and purification of the oil with a view to devising a satisfactory procedure for obtaining the active material in reasonably pure form. In preliminary chemical studies the oil was found to decolorize readily aqueous potassium permanganate and bromine in carbon tetrachloride. This behavior along with other results suggests that the antibiotic may be an unsaturated carbonyl compound containing only carbon, hydrogen, and oxygen. Further chemical studies are in progress.

SUMMARY

1. A light yellow, water-insoluble oil possessing antibiotic properties has been obtained in high yield by the ethyl acetate extraction of the macerated root of *L. multifida*.

2. The oil showed considerable activity *in vitro* against the five Gram-positive organisms and also against certain of the nine Gram-negative bacteria tested.

3. Penicillin G and the crude or the water washed extract at concentrations of 10^{-2} were roughly comparable in agar plate tests in antibacterial activity against the Gram-positive and Gram-negative organisms sensitive to both.

4. Complete inhibition of acid-fast organisms, including *M. tuberculosis*, var. *hominis*, by the extract was observed at a concentration as low as 10^{-4} in mineral oil.

5. A procedure involving regeneration of the sodium bisulfite addition complex of the oil resulted in a purified material having substantially enhanced bactericidal activity.

6. Water washed or bisulfite purified extract showed no visibly noticeable toxic effect in mice when relatively large doses were given subcutaneously.

7. Preliminary chemical studies suggest that the oil may be an unsaturated carbonyl compound containing only carbon, hydrogen and oxygen.

FACTORS INFLUENCING THE ANTIBIOTIC ACTIVITY OF LUPULON^{1, 2, 3}

BY YIN-CH'ANG CHIN, NAI-CH'U CHANG,⁴ AND HAMILTON H. ANDERSON
(Division of Pharmacology and Experimental Therapeutics, University of California Medical
School, San Francisco, California)

Lupulon is one of the two lipid-soluble antibiotics prepared from hops (*Humulus lupulus* L.) (1, 2). Michener *et al.* reported antifungal activity for both lupulon and humulon. Salle *et al.* (3) confirmed Shimwell (4), that Gram-positive organisms are more susceptible to lupulon than are Gram-negative bacteria. Chin *et al.* (5) reported its antituberculous activity both *in vitro* and *in vivo*. These findings and its relatively low toxicity (6) indicated that lupulon may be an effective chemotherapeutic agent. It becomes, therefore, desirable to investigate some important factors which may influence its activity either *in vitro* or *in vivo*.

MATERIALS AND METHODS

Crystalline lupulon used throughout this experiment was prepared at the Western Regional Research Laboratory, Albany, California. One % solution can be made in alkaline water at pH around 11.5 or by dissolving the crystals first as 10% solution in ethyl alcohol and then diluting up to volume with propylene glycol. The antibiotic activity has been found to be the same whether the solution was first made in alkaline water or in propylene glycol. The latter solution has a pH at 4.8 and has been used, freshly prepared with aseptic precautions, as the stock for further dilutions in alkaline water, serum, or culture media.

Staphylococcus aureus (FDA No. 209), *Mycobacterium phlei*, and *Mycobacterium tuberculosis* H37Rv were used in the experiments. Unless otherwise mentioned, veal-glucose broth (7) was used for growth of and tests on *Staph. aureus*, and Dubos and Davis fluid medium (8) for the mycobacteria. The Coleman junior spectrophotometer was used for turbidimetric determinations of the growth of organisms.

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

³ Supported, in part, by Eli Lilly and Company, Indianapolis 6, Indiana.

⁴ Peiping Union Medical College Fellow in Pharmacology.

RESULTS

Effect of size of inoculum. The effect of the size of inoculum of *Staph. aureus* on the antibiotic activity of lupulon was studied with the serial dilution method. Two-fold dilutions of the antibiotic were made in 0.5 ml. of the medium in nine 10-cm. test tubes, starting from a concentration of 200 µg./ml. A tenth tube containing the same amount of the medium served as the control in a series. Each tube was then inoculated with 1.5 ml. of a diluted 24-hour culture. Each of four different dilutions, namely, 1:100, 1:1000, 1:10,000, and 1:1,000,000, was inoculated to one series of tubes. The tubes were incubated at 37° C. and observations were made four, 24, and 48 hours later. The results are shown in Table I where even a faint growth was recorded positive.

Apparently the end point of no growth varied with the concentrations of the inoculum and also the time when the observation was made. Repeated experiments showed that observations at four hours after inoculation gave consistent end point at 1:640,000 or 1.56 µg./ml. in the series where the concentration of the inoculum was 1:1,000 of a 24-hour culture. This size of inoculum and time of incubation have been adopted in later experiments where serial dilution method was used.

Effect of constitution of medium. The serial dilution method was used to determine the bacteriostatic level of lupulon against *Staph. aureus* in three different media. These media,⁵ namely,

⁵ The compositions of these media are given below:

Modified Dubos and Davis medium:	
Casein hydrolysate	1.0 gm.
Na ₂ HPO ₄ ·12H ₂ O	6.3 gm.
KH ₂ PO ₄	1.0 gm.
Na ₂ citrate·2H ₂ O	1.5 gm.
MgSO ₄ ·7H ₂ O	0.6 gm.
Distilled water to	1000.0 ml.
Beef heart infusion broth:	
Beef heart	5.0 gm.
Difco neopeptone	1.0 gm.

	48	—	—	—	—	++	+++	+++	+++	+++	+++

modified Dubos and Davis medium, a beef heart infusion, and veal-glucose broth, had been shown by turbidimetry to support the growth of *Staph. aureus* to different extents. It was found, however, that the growth was completely inhibited by lupulon at the same concentration, 1.56 $\mu\text{g./ml.}$, no matter in which medium this antibiotic was incorporated.

Effect of pH

Studied with Staph. aureus. Veal-glucose medium was titrated to pH's 7.1, 7.6 and 8.1. For each pH duplicate series of six tubes were used. Into each of the six tubes in a series, 3 ml. of the medium was dispensed, containing an appropriate amount of lupulon so that after the inoculum was added to it the final concentrations of lupulon were 0, 0.2, 0.4, 0.6, 0.8, and 1.0 $\mu\text{g./ml.}$ An inoculum consisted of 3 ml. of 1:50 dilution of a 24-hour culture so that the final concentration of the bacteria in each tube was 1:100 of the culture. The growth in each tube was measured turbidimetrically after four hours incubation at 37° C. The results, as shown in Figure 1, indicated greater inhibitory power of lupulon at lower pH.

Plate-well assay was performed by following Pratt and Dufrenoy's method (9), with some

NaCl	5 gm.
Distilled water	1000.0 ml.
Veal-glucose broth:	
Veal infusion	500.0 gm.
Bacteriological peptone	10.0 gm.
NaCl	5.0 gm.
Dextrose	1.0 gm.
Distilled water	1000.0 ml.

modifications. The inoculum of *Staph. aureus* of the top agar was 2%. The inhibition zones were measured after overnight incubation at 37° C., and the staining processes with 1% potassium ferricyanide and 1% ferric sulfate were applied only when necessary. Dilutions of lupulon were made in alkaline water adjusted to pH's 7, 8, 10, and 11.5. The inhibition zones produced by 50, 20, 10, and 5 $\mu\text{g./ml.}$ were fairly consistently 28, 24, 21, and 18 mm. for respective concentrations at all pH's.

Studied with M. phlei. Dubos medium used in this experiment was titrated to pH's 5, 6, 7, and 8. The concentrations of lupulon in duplicate series of tubes were 0, 30, 35, 40, 45, 50, 55, 60, 70, and 80 $\mu\text{g./ml.}$ The inoculum was made so that the final concentration of bacteria in a tube was 1:100 of a 48-hour culture. The end points, taken as the concentration in which no growth occurred after 24 hours incubation at 37° C., were 50 $\mu\text{g./ml.}$ for pH 7 and 8, and 40 $\mu\text{g./ml.}$ for pH 5 and 6.

Studied with M. tuberculosis (H37Rv). The experiment was performed in a similar manner to that with *M. phlei*. The concentrations of lupulon in a series of tubes were 0, 5, 10, 15, 20, 25, 30, and 40 $\mu\text{g./ml.}$, and the inoculum was 0.05 ml. of 14-day culture to a volume of 5 ml. of the medium. End points were taken at the end of 72 hours: At pH 7 and 8 it was 25 $\mu\text{g./ml.}$; at pH 6, 15 $\mu\text{g./ml.}$ The organisms did not grow well at pH 5.

Effect of NaCl

Studied with Staph. aureus. The veal-glucose medium contains 0.5% NaCl. The salt concen-

tration was also increased to 1 and 2%. Since NaCl itself at concentrations higher than 2% inhibited partly the growth of the bacteria, they were not included in this experiment. The results of the turbidimetric measurements indicated that 2% sodium chloride increased slightly the activity of lupulon (Figure 1).

Plate-well assay showed no influence of 0.5, 1, 2, and 5% NaCl on the activity of lupulon when the salt was incorporated in the lupulon solutions. However, as illustrated in Table II slightly larger inhibition zones were produced by the same concentrations of lupulon when the salt was incorporated in the agar plates.

antibiotic activity of lupulon against *M. tuberculosis* (H37Rv) (Table III).

Effect of serum

Studied with M. tuberculosis (H37Rv). Pooled human serum, Seitz-filtered and inactivated at 56° C. for 30 minutes, was added to Dubos medium at three different concentrations, namely, 5, 7, and 10%. Similarly treated horse serum was used at 10%. Since Dubos medium containing 20% of either human or horse serum became turbid and then produced sediments after 24 hours incubation at 37° C. which interfered with reading the end points, this concentration was not included in the present study. The results of repeated experiments by serial dilution method showed consistently that the growth of tubercle bacilli was completely inhibited by lupulon at a concentration of 1:40,000 or 25 $\mu\text{g./ml.}$ regardless of the presence of either serum up to 10%.

Studied with M. phlei. Table IV shows the effect of various concentrations of inactivated horse serum on the bacteriostatic level of lupulon against *M. phlei*. In the presence of 10% serum the growth was completely inhibited by 70 $\mu\text{g./ml.}$ instead of 50 $\mu\text{g./ml.}$ in its absence. There was, therefore, an apparent 30% reduction of the activity.

Studied with Staph. aureus. By the serial dilu-

tion method, using 1:1,000 dilution of 24-hour culture for inoculation, the concentration of lupulon which caused complete inhibition of growth of this bacteria in veal-glucose medium containing 10% inactivated horse serum was 12.5 $\mu\text{g./ml.}$ in contrast to 1:640,000 or 1.56 $\mu\text{g./ml.}$ in the absence of the serum. The activity of lupulon was apparently reduced to about one-tenth of its original level.

Turbidimetric and plate-well assay were then performed to give this effect a further analysis. In turbidimetry, six duplicate series of six tubes containing various amounts of lupulon were prepared as described previously in this paper. In five of such series the medium contained five different concentrations of inactivated horse serum, namely, 50, 20, 10, 5, and 2%. The sixth series served as the control without serum. The results, as shown in Figure 2, indicated that there was a reduction of the activity of lupulon to one-tenth. The growth of *Staph. aureus* was practically not inhibited by lupulon in the presence of 50% serum.

For plate assay, 0.9% NaCl was adjusted to pH 11.5. Inactivated horse serum was added to it at 2, 10, and 50%. Lupulon was diluted in these solutions at 50, 20, 10, and 5 $\mu\text{g./ml.}$ It was also diluted in 100% serum as well as the saline without serum. The inhibition zone was plotted against the logarithm of the concentrations (Figure 3). That produced by 50 $\mu\text{g./ml.}$ in 100% serum was of approximately the same size as one produced by 5 $\mu\text{g./ml.}$ in saline. The inhibitory power of lupulon in 10% serum was about 30% of that in its absence; in contrast, only one-tenth was found in the fluid medium as determined by serial dilution or turbidimetric method.

The apparently dissimilar effect of serum on the antibiotic activity of lupulon against different bacteria as well as against the same bacteria in dif-

FIG. 3. EFFECT OF HORSE SERUM ON ACTIVITY OF LUPULON BY PLATE-WELL ASSAY AGAINST *Staph. aureus*

ferent media indicated that the effect was unlikely exerted on the antibiotic itself. This point was substantiated by the following experiment.

A 1,000 $\mu\text{g./ml.}$ solution of lupulon in inactivated horse serum (A) and another in alkaline water (B) were made from 1% propylene glycol solution. After 24 hours, a fresh solution of each (C and D) was prepared from the same propylene glycol solution. Thirty minutes later, equal volumes of 95% ethyl alcohol were added to all tubes, and those containing serum were centrifuged to separate the precipitates. The supernatant fluid and the alkaline-alcohol solution were diluted to 50, 20, 10, and 5 $\mu\text{g./ml.}$ of lupulon, calculated on the basis of the amount originally added to the solutions before adding ethyl alcohol. A series of alkaline solutions (E) diluted from the same propylene glycol preparation and another series of similar dilutions of the solvents only (F) served as controls. Each series of dilutions was assayed by duplicate plates. It was definitely shown (Table V) that all the activity of lupulon was retained in the supernatant fluid. It is, therefore, believed that whatever the serum contained which produced the apparent reduction in the activity of lupulon had been removed by precipita-

tion with 48% ethyl alcohol. When the same supernatant and alkaline-alcohol solutions were tested by serial dilution method the same end points were obtained.

DISCUSSION

Just how far the design of *in vitro* experiments on antibacterial agents can simulate the conditions *in vivo* is not certain. However, a study of the effect of such factors as pH, sodium chloride, and serum gives information regarding the activity of these agents before or when they act on bacteria. Such a study on lupulon has indicated that at the pH, the concentration of sodium chloride, and the presence of serum, which are normal to the body, this antibiotic remained active.

Lupulon is less soluble in water but more so in lipids at low pH. The greater partition coefficient, therefore, may serve as an explanation for its availability to the bacterial cells (10) and thus its greater antibacterial activity at lower pH. Penicillin is also more active at lower, and less at higher pH, which Abraham and Duthie (11) suggested as an explanation of the action of penicillin by competition with OH^- ions for position on the cell surface in order to produce its effect. A similar theory might be suggested also for lupulon on account of the above-mentioned facts.

Addition of sodium chloride to the media increased slightly the antibiotic activity of lupulon. In no case was it decreased, although the presence of the salt in lupulon solution assayed on plates produced no effect at all. Such minor discrepancy may be explained on the basis of a difference in the rate of diffusion as in the case of streptomycin (12).

That lupulon is not inactivated by serum has been shown by the fact that it retained activity after standing in serum solution for 24 hours. The apparent effect of serum on the antibiotic activity must be explained either by a change of sensitivity of the bacteria or by the presence of some antagonizing factors in the serum. No attempt has been made to elucidate this point. However, it is known that the apparent effect could be removed by treating solutions with 48% ethyl alcohol, whatever its causal agent may be. It is unlikely that the effect was due to growth promotion by serum, because it has been found that the same

Solvent controls (F)	0	0	0	0

bacteriostatic level of lupulon against *Staph. aureus* was obtained from three different media which supported its growth to varying degrees.

The apparent activity of streptomycin varied inversely with the size of inoculum, which Berkman *et al.* (13) explained to be due to the presence of a greater number of resistant organisms in a larger inoculum. This explanation has been adopted here, with reservation, for a similar finding with lupulon.

SUMMARY

Lupulon inhibits the growth of *Staph. aureus* (FDA No. 209), *M. phlei* and *M. tuberculosis* (H37Rv) at a concentration of 1.56, 50, and 25 $\mu\text{g./ml.}$, respectively. In the case of *Staph. aureus* a higher concentration is required for a larger inoculum. It is more active at low pH. Sodium chloride at a concentration of 2% increases slightly its activity.

Its potency against *M. tuberculosis* is not affected by 10% horse or human serum. However, a 30% decrease has been observed under the same conditions for *M. phlei*. The activity against *Staph. aureus* has been estimated by serial dilution and turbidimetric methods to be reduced to one-tenth of its original level in 10% horse serum. By plate-well assay a similar reduction has been observed in 100% serum. All the activity of lupulon has been found to be retained in the supernatant fluid after precipitation of proteins from solution in horse serum with 48% ethyl alcohol. These observations argue against any inactivation of lupulon by serum.

The results of this experiment indicate that under the conditions of the pH, the concentration of sodium chloride, and the presence of serum, which

are normal to the body, lupulon should remain active.

LUPULON AND HUMULON—ANTIBIOTIC CONSTITUENTS OF HOPS¹

By J. C. LEWIS, GORDON ALDERTON, J. F. CARSON, D. M. REYNOLDS,
AND W. D. MACLAY

(From the Western Regional Research Laboratory,² Albany, Calif.)

Commercial hops, the dried cones of the hop vine (*Lupulus humulus*), contain two antibacterial agents, lupulon and humulon. Methods of preparation of the compounds, their chemical structures, and their inhibitive action against Gram-positive bacteria have been known for many years; nevertheless, their antibiotic properties have been largely ignored in relation to animal infections. Their relatively high content in such an accessible source, together with the availability of simple methods for their isolation, prompted a survey of the antibiotic spectra of the substances. Lupulon and humulon were supplied to Dr. H. H. Anderson of the University of California Medical School for the determination of their activity toward *Mycobacterium tuberculosis*. The ensuing demonstration by Chin *et al.* (1) that lupulon inhibits the growth of a virulent strain of this pathogen *in vitro* and exerts a pronounced effect on experimental tuberculosis infections in mice has quickened interest in the microbiological, pharmacological, and therapeutic investigation of these agents.

The Western Regional Research Laboratory has been engaged recently in the determination of the antibiotic spectra of lupulon and humulon, development of methods by which substantial quantities of each can be readily prepared, determination of a number of their physical and chemical properties, preparation of certain derivatives, and development of methods of assay.

CHEMICAL AND PHYSICAL PROPERTIES

Structure. The formulas given in Figure 1 for lupulon and humulon had been established by 1926

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

² Bureau of Agricultural and Industrial Chemistry, Agricultural Research Administration, U. S. Department of Agriculture.

through the investigations of Wieland (2) and Wöllmer (3) on the basis of degradative reactions summarized in von Richter's Organic Chemistry (4). The agents have not been synthesized.

Solubility and stability. Both lupulon and humulon are fairly soluble in polar and non-polar organic solvents such as methanol, ethanol, petroleum ether, hexane, and iso-octane. Both are only slightly soluble in neutral or acidic aqueous solution but are readily soluble as the sodium salts.

Lupulon is moderately stable to both acid and alkali. At room temperature in the presence of air it is very labile. In the crystalline form, it may become yellow and amorphous within a few days. This change is much slower at 5° C. in air; storage for several months is accompanied by development of a characteristic odor, though color development is not marked. Lupulon crystals appear perfectly stable *in vacuo* even at 60° C. Recently, Lundin (5) has reported that oxidation of lupulon (and humulon) is promoted by daylight and by metal oxides and that the oxidation is much more rapid in petroleum ether than in alcohol. F. Stitt and G. F. Bailey of this Laboratory have found that the ultra-violet absorption spectra of very dilute solutions of lupulon in petroleum ether or in iso-octane change very rapidly on standing at room temperature, but similar solutions in methanol or water have more stable spectra.

FIG. 1

Humulon: R = —OH
C₂₁H₃₂O₈, MW 362.3, m.p. 55°, [α]_D — 232°, monobasic acid.

Lupulon: R = —CH=CHCH(CH₃)₂
C₂₃H₃₄O₈, MW 414.3, m.p. 92°, optically inactive, monobasic acid.

Michener and Andersen (6) of this Laboratory found that the addition of 0.1% of ascorbic acid exerted a marked protective action on the bacteriostatic activity of lupulon steamed or autoclaved at a concentration of 4 ppm. in phosphate buffers at pH 6.5 and 8.5.

Humulon is relatively stable to acid. The lead salt is stable, but the *o*-phenylenediamine salt slowly turns brown at room temperature in air, but not *in vacuo*. In aqueous solution at neutrality, or particularly in alkaline solution, humulon is transformed by boiling to an unidentified product which is not precipitable by lead acetate but which is believed by Walker (7) to retain some antibacterial activity. Quite recently, Verzele and Govaert (8) have reported the chromatographic separation of the immediate transformation product of humulon ("isohumulon"). They state that on boiling in methanol solution, humulon is quantitatively converted to isohumulon. On boiling with aqueous alkali, they found isohumulon to be converted to humulinic acid. Humulinic acid has been prepared in this Laboratory by boiling humulon with 1 *N* NaOH (2). It proved to be antibiotically inactive.

Michener and Andersen (6) found no loss of bacteriostatic potency against *Staphylococcus aureus* when 40 ppm. of humulon in phosphate buffer at pH 6.5 or 8.5 was autoclaved. However, the presence of low concentrations of ascorbic acid extended the duration of bacteriostatic action of humulon as well as that of lupulon.

METHODS AND RESULTS

Assay

Lupulon in simple solutions may be determined by its inhibitive action on Gram-positive bacteria in turbidistic or cup-plate tests. A reduction of the bacteriostatic action of lupulon by blood serum, the mechanism of which is being investigated at this Laboratory by L. E. Sacks, prevents the use of such a method for determination of lupulon in blood and other tissues.

A tentative spectrophotometric method of analysis for the lupulon and humulon content of hop extracts has been developed by F. Stitt and G. F. Bailey of this Laboratory and will be described in a coming publication.

Isolation of hop antibiotics

Lupulon. Lupulon has been isolated on a kilogram scale in this Laboratory. The method is essentially that devised by Bungener in 1886. High-quality hops are

necessary, since lupulon is unstable and since quantitative yields are not obtained by this process.

The hops, ground with an equal weight of dry ice to reduce the stickiness of their resinous content, are extracted with petroleum ether (30–60° C.) in a column, or in countercurrent fashion in several columns. The petroleum ether extract is concentrated without delay *in vacuo* to a thin syrup, which is then placed at approximately –15° C. to crystallize. A rich extract may form a single porous cake so that the mother liquor can be drained off directly, or the crude crystals are filtered on a cold Büchner funnel. The crude crystals are then dissolved in warm petroleum ether (approx. 150 g. per l. at 40° C.), and recrystallized by chilling with stirring in a dry ice bath. The process is repeated twice, and then the lupulon is dried and dissolved in methanol (approx. 150 g. per l. at 20–25° C.). A white insoluble impurity is filtered off, and the lupulon is recrystallized by the slow addition of 1/10 volume of water and overnight storage at 0° C. The recrystallization from 90% methanol is repeated twice. High-quality hops yielded 3% of once-recrystallized and 1.5% of 6 × recrystallized lupulon, compared to the weight of the air-dry hops.

The product consists of fine white crystals, optically inactive, with theoretical C and H contents, and melting at 92–94° C. The lupulon crystals are stored *in vacuo* in the cold. Samples are distributed in evacuated ampules.

Humulon. The conventional method for the isolation of humulon by precipitation as the lead salt has been greatly simplified in this Laboratory by making the first precipitation with *o*-phenylenediamine from the crude petroleum ether extract of hops (usually from the mother liquor remaining after the crystallization of lupulon). *o*-Phenylenediamine was first used in 1916 by Wöllmer (3) for the purification of humulon lead salt. To our knowledge it has not been used previously for the direct isolation. Eighty % recovery is obtained. Free humulon can be obtained by acidification and extraction with an immiscible organic solvent such as ethyl ether.

Antibiotic spectra of humulon and lupulon

The antibiotic spectra of humulon and lupulon given in Table I have been determined in this Laboratory by the quantitative agar-streak dilution method of Waksman and Reilly (9). The antibiotics were dissolved in 1% concentration in 95% ethanol, and by means of aqueous dilutions, decreasing amounts were added to a series of 10 cm. Petri dishes, i.e., 1.0, 0.3, 0.16, 0.1, 0.03, etc., ml. per dish. The lupulon used was a preparation recrystallized three times. Humulon was tested in two forms, namely the *o*-phenylenediamine salt and humulon prepared from the above salt two hours before the test.

The test medium for bacteria and yeasts was nutrient agar (0.5% Difco peptone, 0.3% Difco meat extract, 0.5% NaCl, and 1.5% Difco agar in tap water, pH 7.0, autoclaved at 121° C. for 20 minutes). For fungi other than yeasts, potato dextrose agar was employed. Melted and cooled (45° C.) 10 ml. portions of the medium were added to plates, which were immediately and thoroughly

rocked to disperse the antibiotics. After about 30 minutes, cell suspensions from 24-hour-old cultures of the test organisms were streaked onto the solidified plates, each within a designated sector. Each sector received three streaks made with an L-shaped needle without recharging.

With bacteria-streaked plates, incubation was carried out at 35° C. for 18–20 hours, except for *Sarcina lutea*, the mycobacteria and the actinomycete, which were incubated for two days. Yeasts and other fungi were incubated at 30° C. for three days. After incubation, the results of growth were recorded and compared with control plates lacking the antibiotic. The inhibitory endpoint was taken as that dilution of the antibiotic which completely or nearly completely inhibited growth of the test organism. To reduce error, each spectrum was run five to ten times on different days, with replicate dilution plates each day.

Humulinic acid was found to be inactive at 0.1% for *Escherichia coli*, *Micrococcus conglomeratus*, *Micrococcus pyogenes* v. *aureus*, *S. lutea*, and *M. tuberculosis* v. *hominis*.

The inhibitive action of hop extracts towards bacteria has long been recognized and turned to practical use in brewing and in preservation of unpasteurized beer. In 1937 Shimwell (10) pointed out that Gram-negative bacteria would

grow as readily in hopped as in unhopped beer worts, whereas Gram-positive bacteria grew not at all or very poorly in hopped wort. Walker and Parker (11) presented data which showed that 0.8 ppm. of humulon or 0.2 ppm. of lupulon give 50% inhibition of acid production by a strain of *Lactobacillus bulgaricus* inoculated into grain wort at pH 4.5. Hansen (12) found pure humulon and lupulon to exert no inhibitive action at 50 ppm. on several species of *Saccharomyces*, on *E. coli*, *Eberthella typhosa*, and *Salmonella paratyphus* A and B. Both *Staph. aureus* and *Bacillus mesentericus* were inhibited at 12 and 2 ppm. of humulon and lupulon, respectively, while germination of spores of *Bacillus subtilis* was inhibited by 4 and 0.5 ppm., respectively. Michener, Snell, and Jansen (13) found that humulon and lupulon possess a low order of antibiotic activity against a panel of plant pathogenic fungi. Yeasts were largely unaffected.

The tuberculostatic action of lupulon was first noted by Chin *et al.* (1) and confirmed by Salle *et al.* (14) and by ourselves (see above). Chin found lupulon active against the H37Rv strain of *M. tuberculosis* at 1:40,000 in Dubos' medium, while Salle found the same strain inhibited by 1:200,000 in Long's medium and in Proskauer and Beck's medium, and by 1:90,000 in Dubos' medium. Humulon was much less active, and was not tested further.

The possibility of the development of lupulon-fast strains of Gram-positive and acid-fast bacteria has not been investigated as yet, but the brewing literature contains references to the "acclimatization" of Gram-positive bacteria to beer wort.

Serum has been found by Salle *et al.* (14), by Chin *et al.* (15), and by ourselves to reduce the bacteriostatic action of lupulon *in vitro*. In serial dilution tests with *Staph. aureus* and *M. conglomeratus* in broth containing 0.7 or 7% of serum, we found approximately 50 µg. of lupulon to be inactivated per ml. of undiluted serum. In cup-plate tests with *Mycobacterium phlei* and *B. subtilis*, 9 ppm. of lupulon in 10% serum gave zones equivalent to those given by 2 ppm. of lupulon in water.

Although inactivation by serum *in vitro* might by present concepts eliminate an antibiotic from further consideration for internal and other applications, such an effect does not prove a lack of therapeutic

tic value. In fact, the positive influence of lupulon administered orally or intramuscularly in oil on mouse tuberculosis as described elsewhere (1) suggests that otherwise promising tuberculostatic drugs if discarded solely because of inactivation by serum *in vitro* should be reevaluated by animal infection tests.

SUMMARY

The isolation, chemistry, assay, and antibiotic spectra of lupulon and humulon have been briefly discussed. A Bureau of Agricultural and Industrial Chemistry Circular of Information entitled "Antibacterial Agents from Hops," in which are summarized the findings of past and present studies of these substances, is now available for distribution.

The Western Regional Research Laboratory is preparing lupulon and humulon in amounts which will allow for distribution on a limited scale to parties interested in their evaluation.

THE OCCURRENCE OF ANTIBACTERIAL SUBSTANCES ACTIVE AGAINST *MYCOBACTERIUM TUBERCULOSIS* IN SEED PLANTS¹

By R. Y. GOTTSHALL, E. H. LUCAS, ARDETH LICKFELDT, AND J. M. ROBERTS

(From the Division of Laboratories, Michigan Department of Health, Lansing, Michigan, and the Michigan Agricultural Experiment Station, East Lansing, Michigan)

For many centuries green plants have been used for the treatment of various diseases. Tuberculosis is no exception, and numerous plants and plant products have, at one time or another, been reported to be of value in the treatment of this disease.

During the past few years a number of investigators have surveyed seed plants for sources of antibacterial activity (1-10). In most of these studies a Gram-positive organism, *Staphylococcus aureus* or *Bacillus subtilis*, and a Gram-negative organism, *Escherichia coli* or *Salmonella typhosa*, were used for detecting antibacterial properties. In some cases the active materials or purified preparations derived from them were then tested against a variety of microorganisms.

In this exploratory survey a strain of *Mycobacterium tuberculosis* was used for assay because of the assumption that some plants might contain substances specifically antibacterial for the tubercle bacillus. These would be missed in any assay using other test organisms. To obtain more information on the antibacterial properties of the extracts, however, most of them were also tested for their effect on *Staph. aureus* and *E. coli*.

Early in the study it was found that some plants contained substances active against the tubercle bacillus but that all or much of the activity was lost in the presence of whole blood. In subsequent tests the active plant extracts were also assayed in media to which blood had been added.

METHODS

Crude plant materials were used for the preliminary screening. The plants were either used in a fresh state immediately after collection, or dried and extracted at a later date. Whenever possible the use of entire plants for

preparation of representative extracts was avoided. In most instances, either leaves or stems or roots or, if the plant was in the stage of flowering, inflorescences were extracted separately. Sometimes different organs had to be combined because of insufficient amounts of material.

The plants tested were green plants, the majority belonging to the subdivision Angiospermae. The system of classification used follows the synopsis of the plant kingdom, published in L. H. Bailey's Standard Cyclopedia of Horticulture (11) and based on "Die Natürlichen Pflanzenfamilien" by Engler and Prantl.

The preparation of the plant material to be tested was essentially the one described by Lucas *et al.* (12). A Waring Blendor was the main tool for the disintegration of the plant parts. However, in the present study extractions with boiling water and with ethanol were made in addition to the customary cold-water extraction. The ethanol extraction followed the technique of the cold-water extraction with the exception that paper was used instead of cheesecloth for the filtration of the macerates. The hot extraction was performed by immersion of the plant materials in boiling water for five to ten minutes, the time depending on the properties of the tissues. All cold-water extracts and any ethanol extracts found to be contaminated were sterilized by passing them through a Seitz filter, boiled preparations by autoclaving.

The extracts were tested for antibacterial properties by making serial dilutions in liquefied glycerol beef extract agar, pH 7.0. The agar was allowed to harden in a slanting position, and after solidification the tubes were inoculated with an 18-to-40-day-old culture of *M. tuberculosis*, strain H37, grown on Petragnani's medium. To prevent evaporation during the long incubation period screw-capped tubes were used for making the cultures. After six weeks of incubation at 37° C. the cultures were examined. If they were inhibited the highest dilution in which no growth occurred was recorded. The active extracts were then retested on glycerol beef extract agar to which 10% whole sheep blood had been added.

With the alcoholic extracts allowance had to be made for the inhibitory effect of the alcohol. This solvent was found to inhibit the tubercle bacillus at a dilution of 1:40 and therefore only extracts in which there was no growth at a dilution higher than this were considered active.

The antibacterial activity of the extracts against *Staph. aureus* (F.D.A. strain 209P) and *E. coli* (SA436) was determined by making serial dilutions in nutrient broth (F.D.A. formula). The broth was inoculated with 1.0 ml. of an 18-to-24-hour broth culture of the organism per 100 ml. of medium just before making the dilutions.

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

Results were read after incubation for 24 and 48 hours at 37° C.

It was found that ethanol inhibited both *Staph. aureus* and *E. coli* at a 1:8 dilution. Consequently only extracts showing an inhibition greater than this dilution were recorded as being antibacterial.

RESULTS

The results of the survey are presented in Table I. They are interesting in many respects. Approximately half the number of species with antibacterial activity against *M. tuberculosis* showed it only against this organism; the others were active also against other organisms. These findings cannot be considered as final since the concentration of the active principles is an unknown factor. It is possible that in some instances materials used merely appeared specific because the antibacterial principle was present in a concentration too low to affect the other or-

Activity against *M. tuberculosis* is indicated by +, ++, or +++, according to potency of extracts. A, B, or C preceding these signs indicates cold water, boiling water, or ethanol extract respectively. Lack of activity is signified by —. Sa and Ec denote activity against *Staph. aureus* and *E. coli*.

Plant parts are designated as follows: Entire plant, E; flowers, Fl; leaves, L; stems, St; roots, R; seeds, Se, and fruits Fr.

ganisms. Nevertheless, by testing the plant extracts against the customary organisms only, half of the materials with activity against the tubercle bacillus would have been overlooked.

Some of the extracts antibacterial for *M. tuberculosis* were tested using for assay the rapidly growing acid-fast strain 607. Only three out of 20 extracts were found to be active against this acid-fast strain.

The materials in which activity against the tubercle bacillus was observed were derived from 27 species, which belonged to 16 families. Eight species belonged to the family Compositae, three to Liliaceae, two to Euphorbiaceae, two to Labiatae. Six of the materials with exclusive activity against *M. tuberculosis* were from Compositae and two from Euphorbiaceae.

Plant leaves were carriers of active principles in most cases. Nine of the 27 plants showed activity in the leaf extracts. In five cases it was found in the extract of leaves and flowers combined while flowers alone showed activity only in three cases. In five plants the activity was found in the roots, and four of the extracts prepared from entire plants inhibited growth of the tubercle bacillus. No activity was recorded in seeds and fruits. Stems and roots combined showed activity in one case. This plant, *Coleus Blumei*, is the only one where extracts of different parts showed specific activities, the leaf extract being active against *Staph. aureus*, the stems and roots against the tubercle bacillus. There were two other cases, one in the same family, where the apparent specificity might be explained by the greater sensitivity of *Staph. aureus* to the active principle. However, in both cases the possibility of the presence of more than one antibacterial principle could not be ruled out.

Only one of the 35 antibacterial plant samples did not show a loss of activity in the presence of whole blood. The other extracts lost all or part of their antibacterial properties in contact with it.

This report is the first in a series involving the investigation of seed plants for principles antagonistic to the tubercle bacillus. Testing of crude materials is being continued. Some of the plant materials, which in the exploratory phase inhibited the growth of *M. tuberculosis*, are under further study.

As Kavanagh (13) very aptly expressed it, "compounds active against more than a few common bacteria must be found, if the potentialities of antibiotic substances as specific inhibitors of microorganisms are to be realized fully. This can be done only by using the organism to be inhibited as the test object in the survey."

SUMMARY

The antibacterial activity against *M. tuberculosis*, strain H37, of 211 plant samples from 161 species belonging to 53 families of seed plants was determined by serial dilution tests. Each sample was extracted separately with cold water, boiling water and ethanol. Twenty-seven species were active, 13 of them specifically against *M. tuberculosis*, while not interfering with the growth of

Staph. aureus and *E. coli*. The activity was found in various parts of the plants, mostly in the leaves.

ACKNOWLEDGMENT

We wish to thank Mrs. J. McCallum and Mrs. R. Engstrom for technical assistance.

A CRYSTALLINE ANTIFUNGAL AGENT, MYCOSUBTILIN, ISOLATED FROM SUBTILIN BROTH¹

By ROBERT B. WALTON AND H. BOYD WOODRUFF

(From the Research Laboratories of Merck & Co., Inc., Rahway, N. J.)

The presence of an antifungal agent in the broth of subtilin cultures has been reported (1). It is not unusual in cultures of aerobic spore formers to find several different antibiotics present. Often, these have been related polypeptides, which have different biological spectra of antibiotic action (gramicidin, tyrocidine, etc.).

This paper reports the isolation and properties of a fungistatic substance from the cells of a culture of *Bacillus subtilis* 370, originally obtained from the Western Regional Research Laboratory of the United States Department of Agriculture, where it was used for studies on subtilin (2). Under certain cultural conditions, fungistatic activity is produced which is not due to subtilin. The standard assay organism for the fungistatic agent, *Trichophyton* sp. MF 301 was not inhibited by 200 μ gm. of subtilin per ml. of agar. The antifungal agent has tentatively been named Mycosubtilin.

METHODS AND RESULTS

Conditions for production

Submerged aerated cultures of *B. subtilis* 370 were grown in 250 ml. flasks containing 50 ml. of 20% beet molasses with 0.8% $(\text{NH}_4)_2\text{HPO}_4$ and 0.005% $\text{MnSO}_4 \cdot 4\text{H}_2\text{O}$ on a shaker rotating at 220 RPM (3). The production of subtilin proceeds at optimum rate at a temperature of 34° C., but a temperature of 25° C. was found more suitable for the fungistatic substance. Yields were better at this lower temperature and filtration and extractions were conducted with greater ease. Fungistatic activity was produced in five days under the foregoing conditions.

Fermented cultures produced in a semi-synthetic medium containing 0.5% yeast extract² gave broth activity equal to that in cultures prepared with beet molasses

medium. Broth samples were usually mixed with three volumes of ethanol to aid extraction of the antibiotic and to sterilize the culture for assay. The agar streak-plate method was used, with *Trichophyton* sp. MF 301 as the test organism, with two-fold dilution levels.

Extraction

The harvested broth was adjusted to about pH 2.5 with concentrated hydrochloric acid to precipitate the cellular material, which was separated by centrifugation. The first extraction of the moist cell solids was made overnight with 95% ethanol, which resulted in a final concentration of approximately 70% ethanol. Subsequent extractions of the cells were made overnight with 70% ethanol solutions. The solids were separated from the ethanol suspensions by filtration. The active fraction was precipitated quantitatively by the addition of two volumes of water and was separated by centrifugation. The solids were successively extracted with 95% ethanol. Material of increased purity was obtained with each successive extract. The ethanol was evaporated to dryness and all of the resulting solids dissolved in a very small quantity of pyridine. White crystalline material was separated during a period of several hours at 10° C. following addition of 10 volumes of water. The crystals were washed with water and recrystallized from 70% ethanol.

It was later observed that the solids from the 70% ethanol extracts of the cells could be directly dissolved in pyridine, thus eliminating the 95% EtOH stages, with better yields. Several recrystallizations were necessary to obtain material which showed a constant melting point and analysis.

The results in Table I represent a typical extraction from a culture produced in beet molasses medium, which had a moist cell volume of 15%.

Properties

The white crystals are practically insoluble in reagents, with the exception of pyridine and 70% ethanol. They are very soluble in the former but show only limited solubility in warm 70% EtOH. The antifungal agent crystallized readily from the latter upon cooling. The crystals are soluble in

justed to pH 6.8-6.9 with NH_4OH and brought to one liter volume. The formula for the semi-synthetic medium and details of the procedures used at the Western Regional Research Laboratory for production of subtilin were disclosed to us by personal communication.

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

dilute cold NaOH but insoluble in dilute cold HCl and cold NaHCO₃.

No precipitate was obtained with 2,4-dinitrophenylhydrazine. There was no reduction of Fehling solution nor color development with ferric chloride solution. Millon's reagent produced a temporary pink coloration and nitration with conc. HNO₃ formed a pale yellow pigment. Acid hydrolyzates gave a strongly positive ninhydrin reaction.

Following recrystallization three times from 70% ethyl alcohol, the crystals melted with decomposition at 256°–257° C. (corr.) on a micro block.³ The crystals gave an analysis of C—55.31, 55.12; H—7.61, 7.33; N—15.15, 15.18. Sulfur was not present. The ultra-violet absorption spectrum of alcohol-water solution consisted of a band at 2770 Å with an $E_{1\%}^{1\text{cm}} = 14.6$. Potentiometric titration showed an apparent combining weight by alkali titration of 1980. General insolubility made the compound unsuitable for molecular weight determination.

Ten mg. of crystalline mycosubtilin was hydrolyzed in a sealed tube with 3 ml. of 6 N HCl at 120° C. for 16 hours. Paper strip chromatography with a phenol-water system, followed by develop-

³ We are indebted to Dr. E. F. Rogers for helpful suggestions and criticisms concerning the chemical characterization. Mr. R. N. Boos performed the elemental analysis and Dr. Charles Rosenblum the UV spectrum and potentiometric titration.

ment with ninhydrin, yielded four distinct zones, with observed R_f values presented in Table II, and an indistinct zone at R_f 0.97, close to the advancing solvent boundary. Amino acids which have characteristic R_f values in the region of the zones observed with mycosubtilin are listed in Table II. Aspartic acid, tyrosine and proline were found to be present by microbiological assay. The natural isomers of the other amino acids listed, with the exception of norvaline and norleucine for which no assays were available, were not found to be present by microbiological assay in concentrations exceeding 5%. The microbiological assay for aspartic acid and alanine is not specific for the natural form. Therefore, it is not certain which isomer of aspartic acid was present and it was demonstrated that the D form of alanine was not present. The tyrosine content is adequate to account for the ultra-violet absorption band described above. It is interesting to note that tyrosine has not been found in subtilin, the other amino acid-containing antibiotic produced by *B. subtilis* 370.

Aspartic acid accounts for nearly one-half the molecule and one-third of the nitrogen. An ad-

ditional one-third of the nitrogen, 5.1% N, was liberated as NH_3 by acid hydrolysis. The speculation arises that aspartic acid is present in the molecule as the amide.

The substance is heat stable, resisting autoclaving in agar for 15 minutes at 120°C . and 15 lbs. pressure.

A concentration of 0.0015 mgm./ml. of agar inhibited the growth of the test organism *Trichophyton* sp. (MF 301) by the streak-plate method on yeast extract dextrose agar. However, the addition of 10% horse serum incorporated in the agar completely neutralized the activity.

Antibiotic spectrum

Micrococcus lysodeikticus was inhibited by 0.001 mgm./ml. of nutrient agar by the streak-plate method. But 0.016 mgm./ml. failed to inhibit *Staphylococcus aureus* (Smith), *Streptococcus pyogenes* C-223, *Streptococcus viridans*, *E.*

coli, *Eberthella typhosa*, *Klebsiella pneumoniae*, *Hemophilus pertussis*, *Corynebacterium diphtheriae* (gravis), *Pseudomonas aeruginosa*, *Mycobacterium tuberculosis* 607, *Salmonella aertrycke*, *Salmonella paratyphi* A, *Salmonella schottmuelleri*, *Alcaligenes faecalis*, and *Bacillus megatherium*.

The yeast spectrum, Table III, and the fungus spectrum, Table IV, were streaked on yeast extract dextrose agar. The results indicate the smallest amount of crystalline material required to cause complete inhibition. Although mycosubtilin is insoluble in water, it does not precipitate when a 10 mgm./ml. solution in hot 70% alcohol is added to liquid agar to make a concentration of 1 mgm./ml.

Toxicity

Toxicity was determined by the subcutaneous injection of mycosubtilin into white Swiss mice weighing approximately 20 gms. each. For injection into mice, a solution containing 2 mgm. of agent per ml. was prepared by mixing an alcoholic solution of the crystalline material with 20% aqueous gelatin. Deaths were observed following single doses of 1 or 0.5 mgm., but single doses of 0.25 mgm. or less were tolerated.

It was impossible to demonstrate the agent in the blood of injected animals because of the neutralizing effect of blood serum on the antifungal activity.

SUMMARY

A fungistatic substance has been isolated from the cells of *B. subtilis*, the subtilin producing microorganism. A method of extraction has been suggested by which crystalline material has been obtained. The white crystals, having a melting point of $256^\circ\text{--}257^\circ\text{C}$. with decomposition, yield amino acids following acid hydrolysis. The new antibiotic has been named mycosubtilin.

THE ANTIFUNGAL ACTIVITY OF ANTIBIOTIC XG¹

By GLADYS L. HOBBY, PETER P. REGNA, NANCY DOUGHERTY,
AND WILLIAM E. STIEG

(From the Biological and Chemical Research and Development Departments of Chas. Pfizer & Co., Brooklyn, N. Y.)

Lewis, Hopper, and Shultz, in 1946 (1), reported the existence of an antimicrobial agent in culture filtrates of an organism closely related to *Bacillus subtilis*, and demonstrated that this substance possesses a remarkable antifungal activity against *Trichophyton gypsum* and certain other pathogenic fungi, as well as against certain of the Gram-positive bacteria. During the following year, Lewis and Hopper undertook to investigate methods of producing this antibiotic on a small scale, and succeeded in recovering a sufficient quantity to permit preliminary study of its biological and chemical properties as well as its therapeutic efficacy in fungous infections in man. These early studies of Lewis and his associates suggested that Antibiotic XG may be a highly effective chemotherapeutic agent in the treatment of fungous infections in man.

The present report will discuss certain of the chemical and biological properties of this new antifungal agent.²

NATURE OF ANTIBIOTIC

Antibiotic XG is produced by the growth of an unidentified organism closely related to *B. subtilis*. The antibiotic may be absorbed from fermentation liquor onto carbon at neutral pH and may be eluted with aqueous acetone. It is soluble in methanol and ethanol. It is insoluble in ether, chloroform, ethyl acetate, and dry acetone.

Antibiotic XG is stable in broth when heated at 90° C. for two hours at pH 3.0; it may be autoclaved at 15 pounds pressure, for at least 10 minutes, at pH 7.0 without significant loss in potency. In wet acetone, it is stable at room temperature

for at least eight months, and in anhydrous alcohol, at a concentration of 3,500 units per cc., it is stable for at least two months.

Antibiotic XG is an amphoteric polypeptide which gels on standing in water. The gel form is biologically inactive but can be reactivated by dissolving in anhydrous solvents. The polypeptide may be hydrolyzed and on paper chromatography shows the presence of several different amino acids.

METHODS AND RESULTS

Standardization

The activity of Antibiotic XG is measured in terms of *T. gypsum* dilution units, one unit being the least amount of antibiotic which will inhibit the growth of a standard strain of *T. gypsum* under controlled conditions. The master standard used for all biological assays of Antibiotic XG has an activity of 70 *T. gypsum* dilution units per mg.³ Preparations having potencies as high as 250 units per mg. have been obtained.

In vitro activity

Methods. The sensitivities of a wide variety of microorganisms to Antibiotic XG were determined in the following manner. Except when otherwise specified, a beef infusion broth (2) buffered at pH 7.8 was used throughout. It was recognized that other mediums, such as Sabouraud's agar, are more commonly used for growth of the pathogenic fungi. It was felt advisable to use the beef infusion broth, however, in view of the fact that it appeared suitable for the growth of both the pathogenic bacteria and fungi.

In the case of all bacteria tested and in the case of *Monilia albicans*, 15-16 hour broth cultures were used except when otherwise indicated. In the case of other fungi than *M. albicans*, suspensions of six to eight day cultures on Sabouraud's agar were used. In all instances, bacterial cultures were diluted in broth to a constant density immediately prior to use. A density allowing 82-86% transmission on a Photovolt Lumatron No. 400 was arbitrarily chosen as standard. Suspensions of the fungous cultures were diluted to approximately the same

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

² The preparations of Antibiotic XG used in this study were prepared in the Biochemical and Chemical Research and Development Departments of Chas. Pfizer & Co., Inc., Brooklyn, N. Y.

* On prolonged incubation sensitivity of this one organism frequently decreased to 90–100 units per cc.

Sensitivity tests were carried out in broth and were read after two days' incubation. Sensitivity was accepted as the least amount of Antibiotic XG causing complete inhibition of growth.

density but clumping of the organisms prevented exact standardization by means of the Photovolt Lumetron.

A graded serial dilution technic was used in all tests. To each 1.8 cc. of serially diluted antibiotic, 0.2 cc. of a 10^{-4} dilution of bacterial culture or 0.2 cc. of an undiluted suspension of fungous culture was added. Incubation was carried out at 37° C. The amount of growth was recorded at 24 and 48 hours in the case of bacteria and at two and five days in the case of fungi. The sensitivity of an organism was accepted as the least amount of Antibiotic XG which would cause complete inhibition of growth, as indicated by absence of gross turbidity. It was recognized, however, that this did not necessarily indicate a bactericidal level.

Results. Antibiotic XG is a highly efficient antifungal agent, active against all strains of pathogenic fungi tested. As shown in Table I, it is active in the presence of serum as well as in its

TABLE II

absence. In general, sensitivities varied little with time of incubation. In the case of *M. albicans*, growth was rapid in the medium used and in this instance sensitivity varied markedly depending upon the length of the incubation period.

The sensitivity of 13 strains of microorganisms, belonging to 10 different bacterial species, is shown in Table II. A temporary bacteriostatic effect was demonstrable against *Streptococcus hemolyticus* (Strain C203 Mv) and against *Diplococcus pneumoniae* (Strain I/230). All other bacteria tested were completely resistant to the action of Antibiotic XG, as prepared in our laboratories.

Mechanism of action

The early studies on the sensitivity of various microorganisms to Antibiotic XG indicated that this antimicrobial agent is strongly fungistatic in nature, and that its action may be affected markedly by changes in the number of organisms present, the concentration of the agent, the temperature of incubation, as well as other factors. To study the effect of Antibiotic XG on certain of the sporulating or slowly-growing pathogenic fungi, by means of growth curves such as are often used in the study of the action of antimicrobial agents on bacteria, seemed impractical. *M. albicans* and a *Rhodotorula*, however, have lent themselves readily to this type of microbiological test.

Methods. Preparations of Antibiotic XG, ranging in potency from 65–100 units per mg., were used throughout these experiments. Growth curves were carried out in the usual manner, as described in a previous communication (3). In certain experiments, all factors were held constant with the exception of the number of organisms; in other experiments, the concentration of drug or the temperature of incubation was varied. In all instances, the number of organisms per cc. at any given time during the incubation period was determined by the pour plate technic.

Effect of concentration of Antibiotic XG on growth of certain pathogenic fungi. The effect of varying concentrations of Antibiotic XG on the growth of *M. albicans*, at 37° C. and at 26° C., is shown in Figures 1 and 2. At 37° C., there was no growth of *M. albicans* when the initial number of organisms was in excess of 1,000,000 organisms per cc. Concentrations of 500–1,000 units of Antibiotic XG were sufficient, however, to produce an apparent fungicidal effect when the initial number

FIG. 1. THE EFFECT OF VARYING CONCENTRATIONS OF ANTIBIOTIC XG ON GROWTH OF *Monilia albicans* (37° C.)

of organisms was in the vicinity of 10,000 organisms per cc. With this number of organisms, 50 units per cc. produced no effect on the growth of the organism. With smaller numbers of organisms, 100-1,000 units produced routinely an in-

itial stimulation of growth followed by a gradual decrease in the number of organisms present. As with larger numbers of organisms, 50 units per cc. was totally ineffective.

The data presented indicate that growth of *M.*

FIG. 2. THE EFFECT OF VARYING CONCENTRATIONS ON ANTIBIOTIC XG ON GROWTH OF *Monilia albicans* (26° C.)

albicans in the medium used is more rapid at 37° C. than at 26° C. In like manner, the action of Antibiotic XG is more complete at 37° C. than at 26° C. No decrease in the number of organisms present was apparent in any instance unless there was also evidence of multiplication.

The effect of varying concentrations of Antibiotic XG on a more sensitive organism than *M. albicans*, namely a *Rhodotorula*, is shown in Figure 3. In this instance, the fungistatic action of Antibiotic XG was apparent even in the presence of an initial concentration of 1,000,000 organisms per cc. Ten to 100 units per cc. was sufficient to produce a gradual decrease in the microbial count. Two units per cc. caused an inhibition of multiplication only, with no actual decrease in number of organisms, while 0.5 unit per cc. allowed full growth. It should be noted that in contrast to *M. albicans*, the *Rhodotorula* produced some multiplication in the absence of Antibiotic XG, under the conditions of this experiment.

Effect of varying concentrations of organisms on the action of Antibiotic XG. In the presence of 1,000 units of antibiotic per cc. of medium, Antibiotic XG exerted a fungicidal action on *M. albicans*, provided incubation was carried out at 37°

C., and provided the initial number of organisms was less than 10,000 per cc. If incubation was carried out at 26° C., a fungistatic effect was apparent, again providing the initial number of organisms was less than 10,000 per cc. With larger numbers of organisms, no fungistatic or fungicidal action on the part of the antibiotic could be demonstrated against *M. albicans*. (See Figure 4.)

Similar results were obtained with the *Rhodotorula*, an organism much more sensitive to the action of Antibiotic XG. In the presence of 0.5–1.0 unit per cc. rapid growth occurred regardless of the number of organisms present. In the presence of 2.0 units per cc., the number of organisms decreased rapidly to zero provided the initial number present was less than 10,000 per cc. It should be mentioned, however, that this does not represent a true fungicidal effect. No growth was observed in pour plates examined after 48 hours of incubation. After incubation for four or five days, however, small numbers of minute colonies appeared, indicating that the antibiotic had served only to suppress the metabolism of the organism. (See Figure 5.)

The effect of hydration on the action of Antibiotic XG. It has been stated previously that An-

FIG. 3. THE EFFECT OF VARYING CONCENTRATIONS OF ANTIBIOTIC XG ON GROWTH OF *Rhodotorula* (26° C.)

FIG. 4. THE EFFECT OF VARYING CONCENTRATIONS OF ORGANISMS ON THE ACTION OF ANTIBIOTIC XG (*Monilia albicans*)

antibiotic XG on standing in water forms a hydrated gel which is biologically inactive. The difference in the activity of the dehydrated active form of the antibiotic and the hydrated gel form was readily demonstrable, as shown in Figure 6. Five hundred units of the dehydrated form per cc., although not completely inhibitory under the conditions of the experiment, were more active than

1,000 units of the hydrated or gel form per cc. The unitage of the latter form was calculated on the basis of the potency per mg. of the same preparation prior to hydration.

Toxicity

Antibiotic XG in its present degree of purity is a strongly hemolytic compound *in vitro*. The tox-

FIG. 5. THE EFFECT OF VARYING NUMBERS OF ORGANISMS ON ANTIFUNGAL ACTION OF ANTIBIOTIC XG (*Exdactylis*—25° C.)

FIG. 6. THE EFFECT OF HYDRATION ON ACTION OF ANTIBIOTIC XG
(*Monilia albicans*—37° C.)

icity of this antimicrobial agent is less than would be anticipated, nevertheless, on the basis of its hemolytic action.

The acute intravenous toxicity in mice has varied from lot to lot. The LD_0 and LD_{50} of aqueous solutions of the most highly purified preparation tested (110 units per mg.) was 5,500 and 9,900 units respectively per kg. mouse. The same preparation when dissolved in saline showed an acute intravenous LD_0 and LD_{50} of 11,000 and 16,500 units respectively per kg. mouse.

Repeated subcutaneous injections of this preparation have indicated that aqueous solutions in dosages of at least 4,100 units per kg. mouse may be administered twice daily for a period of at least five days with no toxic manifestations. (See Table III.)

Rats receiving a single subcutaneous injection of 30,000 units of a less highly purified lot per kg. body weight showed no signs of proteinuria or other toxicity.

Rabbits receiving dosages of 5,000–10,000 units per kg. body weight intravenously, in aqueous solution, in most instances have died promptly after injection. The mortality may be lowered slightly by the use of saline in place of water as diluent for injection. Intravenous dosages of 500–1,000 units per kg. body weight generally cause no reactions. By the intramuscular or oral routes, rabbits tolerate readily 2,000–5,000 units per kg. body weight in either aqueous or saline solutions.

Whether or not the antibiotic actually is absorbed following injection in these animals remains to be determined. Preliminary studies on

TABLE III
Cumulative Toxicity in Mice
Antibiotic XG

4100 q.d.	10	100
4100 bid	10	100
5500 q.d.	10	100
5500 bid	10	60

All animals were treated by the subcutaneous route for five days or until time of death.

the absorption and excretion of Antibiotic XG have suggested that the drug must be absorbed to some extent; the concentrations of antibiotic detected in the serum, however, have been low and erratic. That the antibiotic is bound to or inactivated by plasma protein seems unlikely in view of the fact that the *in vitro* sensitivities of a wide variety of microorganisms to this antibiotic are not altered by the presence of serum. It seems probable that failure to detect larger quantities of Antibiotic XG in serum following parenteral administration is due to the fact that proper assay techniques have not been developed to permit detection of the full amount of antibiotic present in the body fluids.

Chemotherapeutic action

It is difficult to evaluate adequately the chemotherapeutic potentialities of an antimicrobial agent such as Antibiotic XG⁴ by animal experimentation. In general, the fungous infections which occur in man are not readily reproduced in animals. Studies on the chemotherapeutic action of an agent such as this, therefore, can be carried out most satisfactorily directly in man.

The hemolytic action of Antibiotic XG until recently has discouraged its administration by parenteral routes. The fungous group of infections, however, represents one group of diseases in which topical therapy would take care of the great majority of cases. For this reason, Antibiotic XG is of interest despite its hemolytic action. Preliminary clinical studies on the topical and parenteral use of this agent are in progress and indicate (5)

⁴ Antibiotic XG possesses certain properties in common with Bacillomycin as described by Landy *et al.* (4). Comparative studies on the chemical nature of these two compounds and on their biological action are in progress.

that this antibiotic offers considerable promise in the topical treatment of *Monilia* and *T. gypsum* infections as well as in the treatment of a variety of other fungous diseases.

CONCLUSIONS

Antibiotic XG is a highly active antimicrobial agent which exerts a remarkable inhibitory effect on the growth of many of the pathogenic fungi. It is both fungistatic and fungicidal, depending on the experimental conditions used. Its activity is influenced by the number of organisms present, the rate of growth of the organisms, the concentration of antibiotic, and the temperature of incubation. In its present degree of purity, it is hemolytic in nature. Preliminary studies indicate a relatively low degree of toxicity, however, and suggest that with purification and further understanding of the mechanism of its action, it may be possible to administer it parenterally. In its present form, Antibiotic XG offers great promise as a chemotherapeutic agent for the treatment of a group of infections in which local therapy usually is adequate.

NEOMYCIN—PRODUCTION AND ANTIBIOTIC PROPERTIES^{1, 2, 3}

By SELMAN A. WAKSMAN, HUBERT A. LECHEVALIER, AND DALE A. HARRIS

(From the Department of Microbiology, New Jersey Agricultural Experiment Station, Rutgers University, New Brunswick, N. J.)

ANTIBIOTIC SURVEYS

During the last 10 years, a large number of antibiotics which are active against Gram-negative and Gram-positive bacteria, mycobacteria, rickettsiae, and certain of the larger viruses were isolated (1) from various species and strains of the genus *Streptomyces*. This served to focus attention on the actinomycetes as potential producers of antimicrobial agents that might possess promising chemotherapeutic properties. The fact that nearly 20 to 50% of these organisms possess antimicrobial activities served to heighten this interest. Numerous surveys have been conducted. Particular attention has been paid to the formation and isolation of antibiotics that would possess the following characteristics: (a) High activity against Gram-negative bacteria and mycobacteria; (b) antibiotic action against streptomycin-resistant bacteria; (c) low toxicity to animals; (d) other desirable properties, such as activity against rickettsiae, viruses, tumors and phages.

In our own laboratories, large numbers of actinomycetes were isolated from various natural substrates and tested for their antimicrobial activities. The agar-cross-streak method, frequently supplemented by other procedures, was commonly used for screening purposes. Those cultures that proved to be most active were selected and grown in liquid media. Only a small number of these were found capable of giving rise to active antibiotics. The most promising were selected for further studies. For example, of some 300 freshly isolated cultures tested by the above method, only 10 exhibited activities that justified further study.

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

² Paper in the Journal Series, New Jersey Experiment Station, Rutgers University—The State University of New Jersey, Department of Microbiology.

³ These investigations were supported by a grant from the Rutgers Research and Endowment Foundation.

All these cultures proved to be highly active against mycobacteria.

Only few of the cultures, however, that gave good activity by the agar-streak method yielded filtrates which possessed corresponding potency. This may be due to a variety of factors, such as the formation by a single organism of more than one antibiotic or the production of different antibiotics under different conditions of culture. One of these cultures proved to be highly promising and was selected for more detailed investigations. This culture was entered into the Collection as No. 3535. The nature of its antimicrobial spectrum, as compared to corresponding spectra of known antibiotic-producing organisms and measured by the agar-cross-streak method, is shown in Table I. The spectrum of 3535 was found to be quite distinct from those of the streptomycin-producing *Streptomyces griseus* and streptothricin-producing *Streptomyces lavendulae*. The streptomycin-resistant strain of *Escherichia coli* and the Bodenheimer organism were found to be sensitive to the antibiotic activity of 3535; further, the antibiotic

substance produced by 3535 cannot replace streptomycin in making possible the growth of the streptomycin-dependent strain of *E. coli*. The activity of 3535 upon *Bacillus mycoides* and *Bacillus cereus* serves to differentiate this antibiotic from streptothricin. The various mycobacteria were found to be sensitive alike to the antibiotic produced by 3535 and to the other two antibiotics.

METHODS

Formation and isolation of antibiotic 3535

The next steps in the study of the new antibiotic comprised the development of suitable media for its maximum production. Fortunately, media previously found to be best for the production of streptomycin proved suitable. A medium containing 5 gm. peptone, 5 gm. meat extract, 5 gm. glucose, 5 gm. NaCl, 1,000 ml. tap water gave good results. Various modifications were later introduced. The reaction of the medium tended to become acid during the early stage of growth; this favored early lysis of the

culture. This effect was overcome by addition of CaCO₃, as brought out in Table II. This could also be accomplished by increasing the peptone content of the medium to 1 or even 2%, particularly when vegetable peptones, such as soya peptone, were used, or by reducing the sugar content. If sufficient peptone were used, the glucose content could also be increased, with a delaying but favorable effect on the production of the antibiotic. The results of a typical experiment are given in Table III. The addition of a small amount of zinc (1 mg. to 10 mg. ZnSO₄·7H₂O per liter) was later found to exert a favorable

effect, yielding culture filtrates with an activity of 500 to 1,000 u./ml., as shown in Table IV. Larger amounts of zinc proved to be injurious, however. Meat extract could be replaced by yeast extract. Glucose could be replaced by starch in shaken cultures. When distilled water was used, no activity was obtained unless zinc was added.

Aeration proved to be an important factor in the production of the antibiotic, the amount of air required being apparently less than for the production of streptomycin and streptothricin. The reduced aeration could be accomplished by increasing the volume of the medium in the

shaken flasks or by adding a small amount of agar to the medium. A higher temperature (35° C.) was found to be more favorable for rapid formation of neomycin than a lower temperature (26–28° C.); however, a higher level of activity was reached upon prolonged incubation at 28° C.

In measuring the potency or concentration of the new antibiotic, the agar plate dilution method was first used, since it not only allowed determination of the total activity but also tended to establish the antibacterial spectrum of the culture. The agar-diffusion or cup method, which has proved so successful in measuring the potency of other antibiotics, required certain modifications and a well defined standard. This is brought out in the following summary of the effect of different concentrations of antibiotic 3535 upon its antibacterial activity, as measured in terms of streptomycin units:

Concentration of antibiotic 3535 mg./ml.	Activity, as measured in terms of streptomycin u./mg.
1.00	10
0.10	18
0.01	94

When measured by the agar-streak dilution method, the same preparations gave 30 *E. coli* units per 1 mg.

The antibiotic was removed from the broth by procedures similar to those previously found to be effective in the isolation of streptothricin (2) and streptomycin (3).

RESULTS

Antimicrobial properties of antibiotic 3535

The first crude preparations gave an antibacterial spectrum which was quite characteristic of this antibiotic. This is brought out in Table V. One would expect from the results of the agar-cross-streak tests that the new antibiotic would be active alike upon the streptomycin-sensitive and the streptomycin-resistant organisms, as well as upon the streptothricin-sensitive and -resistant organisms. This was actually found to be the case. The high activity of the new antibiotic upon the various mycobacteria proved to be especially interesting. When the sensitivity of the human pathogenic culture of *Mycobacterium tuberculosis* H37Rv and of the streptomycin-resistant strain H37RvR was determined by turbidimetric procedures in the Dubos Tween medium, both cultures were found to be equally sensitive. The new antibiotic was similar to streptomycin in its lack of activity upon fungi.

The differences in the antimicrobial spectra of streptomycin and the new antibiotic, combined with certain chemical differences between the two

‡ Streptomycin-resistant.

antibiotics, emphasized the fact that we were dealing with a new type of antibiotic substance. It was, therefore, designated as *Neomycin*.

Neomycin was found to be less favorable to the development of resistant strains of bacteria on contact with it than is usually found to be the case with streptomycin. A 20-hour-old agar culture of *E. coli* was suspended in water and plated out in nutrient agar containing varying amounts of neomycin. Of 22 billion cells added to each plate, only very few colonies developed. When pieces of agar were removed from the plates and added to sterile media, only the 5 u./ml. plate gave any bacterial growth; the 10 u./ml. and 25 u./ml. agar

plates gave no growth, thus pointing to the high bactericidal properties of neomycin. Figure 1 and Table VI illustrate the difference in the development of bacterial resistance to neomycin and streptomycin.

Plates containing varying amounts of neomycin were streaked with streptomycin-sensitive, -resistant and -dependent strains of *E. coli* (4); the

first two strains were found to be sensitive alike to neomycin, and the last made no growth. This established further the marked difference in antibacterial behavior of neomycin and streptomycin. A comparison of the sensitivity of many strains of the same organism to neomycin revealed considerable variations. Most strains of *E. coli*, for example, were sensitive to 2.5 u./ml.; one

* 1 ml. of 24-hour-old bacterial suspension contained 246 million cells.

strain, however (ATCC 6880), was resistant to 5 u./ml.

When broth or agar cultures of various bacteria containing sufficient neomycin to inhibit growth were incubated for longer periods, no further development of the bacteria occurred, thus pointing to the stability of this antibiotic, as contrasted to aureomycin, for example. Similar results were obtained with saprophytic mycobacteria and the pathogenic *M. tuberculosis*.

Identity of neomycin-producing organism 3535

The neomycin-producing culture was found to be quite distinct in its cultural and other properties from the other known antibiotic-producing species of *Streptomyces*. Its growth on synthetic and organic media was yellowish to brownish, but no soluble pigment was formed, thus placing it among the non-chromogenic forms. Aerial mycelium was readily produced on synthetic media; it was pigmented at first white, turning to rose-pink or flesh-pink or seashell pink (light-russet-vinaceous, according to Ridgway, XXXIX b-9"). On certain media, the mycelium tended to be patchy, gradually covering the surface of the vegetative growth. The sporulating hyphae were usually straight, either forming no spirals or only an occasional loose spiral. Among the type cultures already described in the literature, the above description was found to fit best with the organisms described by Waksman and Curtis as *Actinomyces* (*Streptomyces*) *fradiae* (5).

No. 3535 produced excellent growth in shaken cultures; it frequently tended to undergo lysis, especially in poorly buffered media. It has not

been established as yet whether the lysis of the culture is due to infection with phage or to the action of an autolytic enzyme. In contrast to streptomycin, once neomycin was produced, however, it remained in the medium and was not readily destroyed.

Physical and chemical properties of neomycin

A detailed survey of the physical and chemical properties of neomycin will be presented elsewhere. It is sufficient to summarize some of these properties here.

Neomycin is highly resistant to the action of micro-organisms. It is heat-stable and is resistant to the action of acid (pH 2.0) at the temperature of boiling water.

Neomycin is favored in its antibacterial activity by an alkaline reaction of the medium. The best results were obtained with a pH of 7.0–8.0 of the agar and a pH of 7.0 of the buffer. The presence of glucose in the test medium reduces the potency of the antibiotic by favoring either acid production or growth of test organism.

Cysteine has apparently no marked effect upon the activity of neomycin. When 1 to 10 mg. of cysteine are added to 50 u. of neomycin in a phosphate buffer at pH 7.0 and solutions allowed to stand at room temperature for three to 20 hours, only a slight loss in activity occurs.

SUMMARY

The formation of a new antibiotic, designated as neomycin, by a culture of *Streptomyces* (No. 3535) closely related to *S. fradiae* is reported.

Neomycin is produced, under shaken or submerged conditions, in media similar to those used for the production of streptomycin by *S. griseus*. The culture tends at first to form acid and undergo lysis. This can be prevented by addition of CaCO_3 to sugar-rich media, or by reducing the sugar content of the medium, or by increasing the peptone content. Addition of a small amount of zinc has a favorable effect.

Neomycin belongs to the basic group of antibiotics, which includes a number of substances already described in the literature.

Neomycin is heat-stable. It is also stable to the action of micro-organisms. It is favored in its activity by an alkaline reaction of the medium.

It is not favored by the presence of glucose in the medium.

Neomycin is active against a large variety of bacteria, including Gram-positive and Gram-negative, as well as acid-fast, forms. It is active alike against streptomycin-sensitive and streptomycin-resistant strains of bacteria, including those of *M. tuberculosis* var. *hominis*. It is not active against fungi.

Neomycin is not only bacteriostatic but also strongly bactericidal. It does not readily allow development of resistant strains of bacteria among the sensitive forms.

ACKNOWLEDGMENT

The authors are indebted to Mr. W. P. Iverson of this laboratory for making the determinations of the relative developments of bacterial resistance to neomycin and to streptomycin; to Dr. A. Swart

and Miss D. Hutchison for preparing and isolating some of the neomycin used in these studies.

DIFFUSION PLATE ASSAY FOR CHLORAMPHENICOL AND AUREOMYCIN¹

By W. A. RANDALL, A. KIRSHBAUM, J. K. NIELSEN, AND D. WINTERMERE

(From the Federal Security Agency, Food and Drug Administration, Washington, D. C.)

In the development of bioassay methods for antibiotics a certain standard pattern is usually followed. First, a wide variety of microorganisms are tested for their sensitivity to the new drug and then sensitive strains are selected and tested for their suitability for use in a plate assay, turbidimetric assay and serial dilution assay. Since the Food and Drug Administration tests a number of antibiotics, every effort is made to adapt test procedures for new antibiotics to those already in use. Thus, in the two plate assay methods to be described, it has been found possible to utilize the same test organism; the same medium as that used in the seed layer for the penicillin plate assay; and the general procedure for determining the potency of an unknown which is the same as that described for penicillin in the Federal Register of June 3, 1948.

The percentage error of the assay may be determined by the double dose technic described by Knudsen and Randall (1). A 1:4 ratio is used for chloramphenicol (20 μ g. and 80 μ g.), and a 1:10 ratio for aureomycin (3 μ g. and 30 μ g.). The chart and nomograph for the 1:10 ratio are not given in the above publication but may be obtained on request from the Food and Drug Administration. The percentage error of the chloramphenicol plate assay has averaged 2.23% on about 21 determinations with a range of from 0.7% to 4.58%. The error of the aureomycin assay is somewhat higher. In 24 determinations the percentage error ranged from 2.5% to 14.8% with an average of 7.4%. In our experience the cup-plate method for chloramphenicol is the most accurate and reproducible one yet encountered. A composite curve was prepared from ten daily chloramphenicol curves and the potency of samples previously run recalculated. Since no significant differences in potency were noted, a daily curve is

no longer necessary; however, the composite curve is checked against a new standard curve once every week. A description of the methods follows.

Culture media. Use ingredients that conform to the standards prescribed by the U.S.P. or N.F. Make nutrient agar for the seed and base layer and for carrying the test organism as follows:

Peptone	6.0 gm.
Pancreatic digest of casein	4.0 gm.
Yeast extract	3.0 gm.
Beef extract	1.5 gm.
Glucose	1.0 gm.
Agar	15.0 gm.
Distilled water, q.s.	1000.0 ml.
pH 6.5 to 6.6 after sterilization	

Make nutrient broth, for preparing a suspension of the test organism, as follows:

Peptone	5.0 gm.
Yeast extract	1.5 gm.
Beef extract	1.5 gm.
Sodium chloride	3.5 gm.
Glucose	1.0 gm.
Dipotassium phosphate	3.68 gm.
Potassium dihydrogen phosphate ...	1.32 gm.
Distilled water, q.s.	1000.0 ml.
pH 7.0 after sterilization	

In lieu of preparing the media from the individual ingredients specified above, they may be made from a dehydrated mixture which, when reconstituted with distilled water, has the same composition as such media.

Working standard

A. Chloramphenicol. Weigh out carefully appropriate amounts of the standard which is crystalline synthetic chloramphenicol and dilute in 1% phosphate buffer pH 6 to give a solution containing 100 μ g. per ml. Keep this stock solution at a temperature of 15° C. or less, and use for only one week. From this stock solution make appropriate working dilutions in the above buffer. To facilitate solutions, the standard may be first dissolved in a small amount of ethyl alcohol.

B. Aureomycin. Proceed as above except dilute the aureomycin standard which is crystalline aureomycin to 1000 μ g. per ml. in 1% potassium acid phthalate-tartaric acid buffer pH 3.0 and use for only three days.

Preparation of sample.

A. Chloramphenicol. Dissolve the sample to be tested in a small amount of ethyl alcohol and then further dilute

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

in 1% phosphate buffer pH 6 to make an appropriate stock solution.

B. Aureomycin. Dissolve the sample to be tested in sterile distilled water to make an appropriate stock solution.

Preparation of plates

I. Base layer. Add 21 ml. of agar to each Petri dish (20 × 100 mm.). Distribute the agar evenly in the plates and allow it to harden. Use the plates the same day they are prepared.

II. Seed layer. The test organism is *Sarcina lutea* (P.C.I. 1001). Maintain the test organism on slants of nutrient agar prepared as described above, and transfer to a fresh agar slant once a week. Prepare a suspension of the test organisms as follows: Streak an agar slant heavily with the test organism. Incubate 24 hours at 26° C. Wash the growth off in about 3 ml. of nutrient broth. Use the suspension so obtained to inoculate the surface of a Roux bottle containing 300 ml. of the above agar. Spread the suspension over the entire surface with the aid of sterile glass beads. Incubate 24 hours at 26° C.

A. Chloramphenicol. Wash the resulting growth from the agar surface with about 20 ml. of nutrient broth. If an aliquot of this bulk suspension, when diluted with nutrient broth 1:10, gives a 10% light transmission, the bulk suspension is satisfactory for use in the test. It may be necessary to dilute the bulk suspension so that a 1:10 dilution of an aliquot gives a light transmission of 10%. A photoelectric colorimeter equipped with a filter having a wave length of 6500 Angstrom units is used in the standardization. The bulk suspension may be used in the test for one week or longer. Add 1.5 ml. of the adjusted bulk suspension to 100 ml. of agar which has been melted and cooled to 48° C. Use 4 ml. per plate of this inoculum for the seed layer.

B. Aureomycin. Wash the growth from the agar surface with 50 ml. of nutrient broth. If an aliquot of this bulk suspension when diluted 1:50 in saline gives 75% light transmission (filter same as above), the bulk suspension is satisfactory for use in the test. As above, it may be necessary to dilute the bulk suspension so that an aliquot gives 75% light transmission. The bulk suspension may be used in the test for at least one week. Add 0.3 ml. of the adjusted bulk suspension to 100 ml. of agar which has been melted and cooled at 48° C. Use 4 ml. per plate of this inoculum for the seed layer.

Assay

A. Chloramphenicol. The potency of the sample is determined by the standard curve technic, using a single dose of standard and unknown.

Dilute the sample to be tested to an estimated 50 µg. per ml. in 1% phosphate buffer pH 6. Place six cylinders on the inoculated agar surface so that they are at approximately 90° intervals on a 2.8 cm. radius. Use three plates for each sample.

Fill three cylinders on each plate with the 50 µg. per ml. standard and three cylinders with the 50 µg. per ml. (estimated) sample, alternating standard and sample. At the same time prepare a standard curve, using concentrations of the standard of 30.0, 35.0, 40.0, 45.0, 50.0, 55.0, 60.0, 65.0, and 70.0 µg. per ml. A total of 24 plates is used in the preparation of the standard curve, three plates for each solution except the 50 µg. per ml. solution. The latter concentration is used as the reference point and is included on each plate. On each of three plates fill three cylinders with the 50 µg. per ml. standard and the other three cylinders with the concentration of the standard under test. Thus, there will be seventy-two 50-µg. determinations and nine determinations for each of the other points on the curve. Incubate the plates for 16 to 18 hours at 37° C. and measure the diameter of each circle of inhibition. Average the readings of the 50 µg. per ml. concentration and the readings of the point tested for each set of three plates, and average also all 72 readings of the 50 µg. per ml. concentration. The average of the 72 readings of the 50 µg. per ml. concentration is the correction point for the curve. Correct the average value obtained for each point to the figure it would be if the 50 µg. per ml. reading for that set of three plates were the same as the correction point. Thus, if in correcting the 40 µg. per ml. concentration the average of the 72 readings of the 50 µg. per ml. concentration is 18.0 mm., and the average of the 50 µg. per ml. concentration of this set of three plates is 17.8 mm., the correction is .2 mm. If the average reading of the 40 µg. per ml. concentration of these same three plates is 17.0 mm., the corrected value is then 17.2 mm.

Plot these corrected values including the average of the 50 µg. per ml. concentrations on two-cycle semi-log paper, using the concentration in µg. per ml. as the ordinate (the logarithmic scale) and the diameter of the zone of inhibition as the abscissa. Draw the standard curve through these points.

To estimate the potency of the sample, average the zone readings of the standard and the zone readings of the sample on the three plates used. If the sample gives a larger zone size than the average of the standard, add the difference between them to the 50 µg. per ml. unit zone on the standard curve.

ard curve. If the average value is lower than the standard value, subtract the difference between them from the 50 $\mu\text{g.}$ per ml. unit value on the curve. From the curves read the potencies corresponding to these corrected values of zone sizes.

B. Aureomycin. The assay for aureomycin follows very closely that described for chloramphenicol. The following exceptions are noted.

1. Dilute the stock solution of the sample to be tested to 10.0 $\mu\text{g.}$ per ml. (estimated) in 1% potassium acid phthalate-tartaric acid buffer (pH 3.0).

2. Prepare a standard curve, using concentrations of the standard of 4.0, 6.0, 8.0, 10.0, 13.0, 17.0, 22.0, and 29.0 $\mu\text{g.}$ per ml. in 1% potassium acid phthalate-tartaric acid buffer pH 3.0. The

10 $\mu\text{g.}$ per ml. concentration is the reference point for the aureomycin curve, and the correction point is obtained by averaging the readings of all of the 10 $\mu\text{g.}$ per ml. concentrations.

SUMMARY

1. A cup-plate assay for chloramphenicol and aureomycin is described.

2. The organism, medium and the general method for estimating the potency are the same for both antibiotics.

CHLORAMPHENICOL (CHLOROMYCETIN), AN ANTIBIOTIC. PHARMACOLOGICAL AND PATHOLOGICAL STUDIES IN ANIMALS^{1, 2, 3}

By O. M. GRUHZIT, R. A. FISKEN, T. F. REUTNER, AND EDITH MARTINO

(From the Research Laboratories, Parke, Davis and Company, Detroit, Michigan)

Chloramphenicol is an antibiotic which initially was isolated from culture filtrates of the fungus *Streptomyces venezuelae* (1-3) by Bartz (4) and subsequently was synthesized chemically (5-7).

Chloramphenicol (Chloromycetin) is a pure chemical substance, *D*(-)-*threo*-1-*p*-nitrophenyl-2-dichloroacetamido-1,3-propanediol, and has the following chemical structure

It is a neutral white crystalline substance with a bitter taste and is stable in neutral and acid solutions. The drug is moderately soluble in water (0.25 per cent at room temperature, 0.65 per cent at 70° C and up to 15 per cent in propylene glycol, 5 per cent in 50 per cent acetamide), and is insoluble in vegetable oils. Solubility in urine or serum is about the same as in water. Solutions are stable on heating.

Material for this study consisted of crystalline chloramphenicol obtained from culture filtrates, and the synthetic product.

Chloramphenicol was administered intravenously in aqueous propylene glycol or acetamide solutions to small animals at a rate of 0.1 cc. per ten seconds; dogs received 1.0 to 3.0 cc./min. Acute toxicity results are based on a seven- to 14-day observation period and chronic tolerance studies were carried out for two to four weeks in small animals and for periods of three and five weeks and over four months in dogs. The Dragstedt *et al.* (8) method served to interpolate results.

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

² Chloramphenicol is a generic name coined from the chemical structure of the compound.

³ Chloromycetin is a designated trade mark under which it was originally marketed in the laboratory.

Acute Toxicity

Intravenous administration of a 0.5 per cent aqueous solution of chloramphenicol to 20-gram white mice caused slight transient ataxia with 125 to 150 mg./kg. doses. At lethal or near-lethal doses of 175 to 300 mg./kg., the mice became incoordinated, some were flaccidly prostrate and dyspneic, and death occurred within a few minutes from respiratory failure. The surviving animals appeared normal within a few minutes to one-half hour. Intraperitoneal and oral administration of toxic doses produced similar reactions. Perorally in single doses mice showed a slight dyspnea with 1.5 grams/kg. and dogs were free of reactions at 150 to 200 mg./kg. once or twice daily. Administration of a two-fold increase in the above amounts to dogs produced sporadic vomiting, acute diarrhea, irritability, occasional spasticity and clonic convulsive seizures. The comparative toxicities of the fermentation and synthetic products were nearly identical (Table I).

Intravenous administration of chloramphenicol to adult dogs in 60 to 87 per cent propylene glycol solution at a rate of 3 cc./min. caused transient rise of body temperature of 0.6 to 1.7° F. corresponding to temperature changes from equivalent amounts of propylene glycol alone. The pulse rate had a tendency to become slightly depressed, while the respiration rate increased. A transient hematuria appeared with 150 mg./kg. doses without progressive histopathologic changes in the kidneys. The hemogram was not altered in a seven-day observation period.

When chloramphenicol as a 10 per cent solution in propylene glycol was administered repeatedly at 30-minute intervals, 1 cc. min., intravenously to dogs under pentobarbital anesthesia and the carotid blood pressure and respiratory excursions were recorded by conventional methods,* no alteration in blood pressure or amplitude of excursions and respiratory rate occurred at 125 to 250 mg./kg.

*By Graham Green.

** Renal hemorrhage was frequent.

doses of chloramphenicol. An 11 and 71 per cent decrease in blood pressure occurred with 50 and 100 mg./kg. doses respectively and this was accompanied by slight increase in respiration rate and decrease in amplitude. Single doses to individual animals caused no blood pressure changes with 12.5 and 25 mg./kg., a fall of about 7 to 10 per cent was produced with 50 and 100 mg./kg. Increasing the injection rate had a tendency to cause a "speed-shock" and a 150 mg./kg. dose at 4 cc./min. produced a 97 per cent fall in blood pressure and death from respiratory failure. Analogous volumes of propylene glycol alone caused 5 to 10 per cent fall in blood pressure on repeated injections in the same animal and none when given in single doses to different animals (Figures 1 and 2).

Chronic Toxicity

In chronic tolerance studies different dose levels of chloramphenicol were administered to different groups of mice, guinea pigs, rats, rabbits, and dogs. All animals were observed daily for food consumption, reactions and weekly body weight changes. Blood counts were made on guinea pigs, rats and dogs. The blood non-protein nitrogen, bromsulphalein liver and phenolsulphalein kidney functions, urine analysis for albumin and sugar, and methemoglobin values were determined in dogs. The blood and urinary concentration of chloramphenicol was determined on mice, guinea pigs and dogs.

Urine volume excretion was determined in mice and dogs. The maximal tolerated doses (M.T.D.) which caused no reactions and produced only slight or no depression of normal body weight gain in animals and the 50 per cent lethal doses (LD₅₀) are shown in Table II.

Subcutaneous injections of 50 to 100 mg./kg. twice daily in 10-20 per cent propylene glycol solution to 20-gram mice for 14 days showed a slight to 10 per cent weight gain depression. With 200 and 400 mg./kg. doses, the mice refused food and lost weight, and death of 20 and 100 per cent of animals occurred on respective doses. The sites of repeated injections became indurated and ulcerated. Death was due to anorexia and cachexia, complicated by ulcerations penetrating the abdominal wall.

When chloramphenicol was given to 20-gram mice in the diet, normal growth of animals was maintained on 0.125 and 0.25 per cent concentrations (203 and 385 mg./kg. per day) but with 0.5, 1.0 and 2.0 per cent concentrations (respectively 679, 1290 and 2060 mg./kg. daily) for a two-week period, mice lost from 0.85 to 4.0 grams in weight from anorexia without showing other reactions.

Oral administration to mice by cannula in acacia-water suspension of about 215 mg./kg. twice daily for four weeks caused no anorexia and allowed normal growth rate. A 311 mg./kg. dosage

FIG. 1. INTRAVENOUS INJECTIONS OF CHLORAMPHENICOL IN ANESTHETIZED DOGS

Repeated injections caused no blood pressure changes with 12.5 and 25 mg./kg. A slight depression occurred with 50 mg./kg. and a rapid fall with 100 mg./kg. accompanied by decrease in amplitude and increase of respiratory rate. Increasing speed of injection to 4 cc./min. a 150 mg./kg. dose produced 97 per cent fall in blood pressure and death from respiratory failure.

twice daily produced death of 30 per cent of the animals. It was evident that daily oral intakes in mice of 385 to about 425 mg./kg. in divided doses constituted about the maximal tolerated amounts of chloramphenicol, whether administered in the food or by cannula.

Guinea pigs had considerable aversion to the diet (rabbit chow pellets) (9) containing chlo-

ramphenicol. This was overcome in part by starting animals first on 0.125 per cent (90[±] mg./kg. daily) and increasing the concentration for the second week to 0.25 per cent (153[±] mg./kg.) and to 0.5 per cent (256[±] mg./kg.) in the third week. On this schedule, guinea pigs maintained or increased their weight. When placed initially on a

[±] Actual amount ingested per day.

TABLE II
Chronic toxicity of chloramphenicol

Animal	Mode and duration of administration	M.T.D.	L.D. ₅₀
Albino Mice	In diet ration, daily ingestion for 2 weeks	385	> 2000
	By cannula, in two divided doses daily for 4 weeks	425	> 622
	Subcutaneously in propylene glycol daily for 2 weeks	109	275
	Intraperitoneally in water once daily for 2 weeks	250	> 1000
Guinea Pigs	In diet ration, daily ingestion for 2 to 4 weeks	250 (0.5%)	518 (1.0%)
Dogs	Orally by capsule for 3 and 5 weeks and over 4 months in two divided doses daily	> 200	
	I.M. in propylene glycol for 24 days in two divided doses daily	> 7400	
	Orally by capsule for 7 days in single daily doses	> 500	
Rabbits	I.M. in propylene glycol for 8 days in two divided doses daily	> 100	

FIG. 2. INTRAVENOUS INJECTION OF CHLORAMPHENICOL IN ANESTHETIZED Dog(s)

Single injections of 50 and 100 mg./kg. at a rate of 1 cc./min. caused a slight blood pressure fall (7 to 10 per cent); doubling the injection rate caused the blood pressure to fall about 31 per cent.

0.5 per cent diet concentration, the animals consumed about one-third of the normal food intake for the first week and about three-quarters of normal subsequently. On a 1.0 per cent concentration in the diet, they consumed about one-fourth of normal food intake, lost on an average of 117 grams in weight in two weeks and six out of eight died from cachexia. The two surviving guinea pigs were cachectic, showed a slight hemoglobin concentration (120 per cent versus controls of 104 per cent), with rise of neutrophils to 77 per cent (controls 44 per cent), and the total white cell count remained about unchanged.

Intramuscular Tolerance in Dogs

A group of three young, recently acquired, street dogs weighing 11 to 14 kg. each and showing initial clinical symptoms of "distemper" (a slight body temperature rise, conjunctivitis and serous rhinitis) were each injected intramuscularly twice daily with 0.5 gram of the fermentation process chloramphenicol partly dissolved in 2 cc. of 62 per cent propylene glycol for 38 doses in 24 days. In the first seven to ten days of treatment the temperature of the dogs rose to 103.2 to 106° F. and

receded to normal at ten, 19, and 21 days respectively under treatment. During the fever period the dogs developed anorexia and considerable anemia with 2.5, 3.4 and 4.2 million erythrocytes per cu. mm. respectively. The red cell counts rose to 4.0, 3.4 and 5.5 million as the fever declined and the appetite of the dogs improved. Injections were followed by considerable to severe local tissue induration, extensive edema, hemorrhage and necrosis. Tentatively it was assumed that the anemia was associated with "distemper" and probably the severe local tissue changes were a contributory factor. Autopsy and microscopic tissue examination showed no significant pathologic changes in the liver, spleen, kidneys and other visceral organs, while the lungs showed residual inflammatory foci.

Oral Tolerance in Dogs

Initially 800 mg. or 86 mg./kg. of the fermentation process crystalline chloramphenicol was given to a dog, a single dose orally in a gelatin capsule. The animal remained free of systemic or gastrointestinal reactions. Two dogs were given 300 mg. kg. daily as a single dose for four days. Ani-

mals showed anorexia, lost weight and vomited occasionally. Rise of body temperature of 0.8 to 1.4° F. occurred on the first day; the temperature was normal subsequently. Two other dogs received 200 mg./kg. twice daily for 32 doses in 21 days. These animals developed severe anorexia, adipsia and lost 2.5 to 4.5 kg. in body weight. At the end of the third week the urine showed casts and a large amount of albumin. The body temperature remained normal. Another dog, fed 0.5 gram (73 mg./kg.) twice daily for 38 doses in 24 days, remained asymptomatic. This animal was studied for hematologic, bromsulfalein liver function, blood sugar and total non-protein nitrogen changes. The various test results showed normal values, and the urine remained free of albumin and sugar. Three additional dogs were given 75 mg./kg. twice daily of the fermentation product for 66 doses in 39 days and seven dogs were given synthetic chloramphenicol, 50, 75 and 100 mg./kg. twice daily respectively for 194 doses in 133 days. The dogs of the former group were fed chloramphenicol six days, and the latter five days each week. The daily dosage for each dog was adjusted at weekly intervals to the gain or loss in body weight. The animals of both groups remained in good physical condition; the first group gained 0.55 to 0.85 kg., the second group, 0.45 to 2.75 kg., while two animals remained about stationary (-0.25 to +0.3 kg.). Gastro-intestinal

reactions occurred rarely; one dog vomited once after the 30th dose (50 mg./kg.), the second animal vomited once after each of the 153rd and 166th doses, and a third animal after the 173rd dose (100 mg./kg.). No diarrhea was encountered. The animals showed no disturbances of vision, hearing or somatic reflexes. The urine remained free of sugar and albumin, but occasionally following catheterization injury, blood appeared in urine. The body temperature remained normal except in one animal following catheterization injury and ensuing cystitis. Blood pressures were determined three times on each dog of the second group by an indirect tail plethysmograph method and the readings fluctuated in a normal range of 135 to 165 mm. of mercury, while six untreated dogs showed blood pressure range of 135 to 172 mm. Examination of tissues at autopsy revealed no gross pathologic changes, except focal inflammatory hemorrhagic areas of the urinary bladder of an animal with chronic ulcerative cystitis. Volume of daily urine excretion was in the range of normal dogs.

The hematology in these dogs remained relatively unchanged, although roughly about 300-350 cc. of blood were withdrawn from each dog for chloramphenicol determinations, N.P.N. and blood count studies (Figure 3). In one of these dogs the red cell counts decreased to 4.9 million per cu. mm. and hemoglobin values to 85 per cent. Autopsy revealed ulcerative cystitis and atrophic

FIG. 3. RED CELL COUNTS IN DOGS WHICH RECEIVED CHLOROMYCETIN FOR 194 DOSES IN 134 DAYS AND SUBJECTED TO FREQUENT BLOOD WITHDRAWALS FOR CLINICAL STUDIES REMAINED ESSENTIALLY AT NORMAL LEVELS.

stomach mucosa. The leucocyte counts of treated animals remained in normal range and varied slightly from the pre-treatment values of 7,400 to 15,900, average of 12,400, to the last counts of 10,200 to 14,100 per cu. mm., average of 12,900. The animal with chronic cystitis and atrophic gastritis had an initial count of 18,200 leucocytes per cu. mm. and it remained at this level until the last three weeks when the leucocytes rose to 33,000 and the temperature to 103.3° F. The total blood non-protein nitrogen in the latter animal remained in a normal range (32-46 mg. per cent). The differential counts in the above dogs ranged from 71 to 90 per cent neutrophils prior to chloramphenicol administration and during the treatment period 80 to 90 per cent neutrophils, 10 to 17 per cent lymphocytes and scattered eosinophils and mononuclear cells. No tendency to agranulocytosis or abnormal cell morphology was observed.

The total blood non-protein nitrogen was determined in the morning before dosing, five to nine times on each dog. In this group of dogs the normal values ranged between 19 and 50 mg. per cent. Under chloramphenicol treatment non-protein nitrogen values showed sporadic fluctuation (Table III) which was not parallel to size of dosage or duration of treatment. Moreover, the fluctuation in values was not regularly sustained or cumulative, but paralleled the amount of meat

in the diet ration ingested previous to sampling.

Bromsulfalein liver function tests indicated dye retentions of less than 5 per cent in 30 minutes. Phenolsulfonphthalein excretion amounted to about 58 per cent at one hour as compared with 52 per cent in the pre-treatment period. Daily water intake was reduced by about 50 per cent of normal animals and the urine volume in treated dogs fluctuated from 21 to 32 cc./kg. in 24 hours as compared with 20 to 60 cc./kg. in the normal control period. Anuria was not in evidence, and the renal clearance of creatinine remained normal.

Pathology

Pathologic tissue changes in non-toxic dose range of chloramphenicol were essentially absent. In the toxic range the pathology was related to a "shock-like" effect of chloramphenicol, resulting in prostration, severe respiratory depression or failure, fall of blood pressure, thready pulse, and anoxia. The visceral organs were congested with scattered petechial hemorrhages; the kidneys were moderately swollen and renal hemorrhage occurred on intravenous administration, probably due to propylene glycol (10). The animals either died from respiratory failure within a few minutes after intravenous administration or within two hours on oral administration. The tissues of surviving animals, at the end of the seven-day observation period, on microscopic examination, were essentially free of acute degenerative changes. Tissues of dogs on daily oral intake of 100 to 200 mg./kg. for over four months were free of acute or cumulative chronic degenerative changes except some hydropic changes in capillaries of the glomerulae. Since renal hemorrhage occurred on intravenous administration of maximal tolerated doses of propylene glycol solutions of chloramphenicol, the differential histopathologic changes are under further investigation and will be reported on at a later date.

Blood Serum and Urinary Concentration and Excretion

A four-hour turbidimetric method (11), employing *Shigella sonnei* as a test organism, was used to determine chloramphenicol concentration in blood serum, urine, bile and spinal fluid. One µg./cc. is the threshold of the test sensitivity. In-

travenous administration produced initial blood serum concentration of 17 to 45 $\mu\text{g./cc.}$ at 15 minutes, roughly proportional to 19 and 50 mg./kg. dosage. The serum levels rapidly decreased to below 1.0 $\mu\text{g./cc.}$ at four and six hours respectively (Figure 4). Intramuscular administration in peanut oil suspension of 90 to 101 mg./kg. produced serum levels of 1.5 to 7.5 $\mu\text{g./cc.}$ for a seven-hour period and less than 1 $\mu\text{g./cc.}$ at the 16th hour. When chloramphenicol in propylene glycol was given twice daily intramuscularly in doses of 37 to 46.5 mg./kg., the serum levels varied from 0 to 4 $\mu\text{g./cc.}$ at two hours after the first dose, 3 to 6 $\mu\text{g./cc.}$ at two hours after the second daily dose, and 0.0 to 1.0 $\mu\text{g./cc.}$ on the following morning. Oral administration in dogs of single doses of 86 and 150 mg./kg. provided serum levels from 8 to 39 $\mu\text{g./cc.}$ at two hours, 10.6 to 20 $\mu\text{g./cc.}$ at eight hours and less than 1 $\mu\text{g./cc.}$ at 12 hours. Dogs treated perorally twice daily for over four months were sampled four times at different 24-hour intervals and the average serum levels for an eight-hour period ranged from 6.2 to 9.8 $\mu\text{g./cc.}$ for the 50 mg./kg. dose, 19.1 to 25.8 $\mu\text{g./cc.}$ for the 75 mg./kg. dose and 26.6 to 36.4 $\mu\text{g./cc.}$ for the 100 mg./kg. dosage. The blood

serum contained no chloramphenicol 18 hours after the second daily oral dose. Bile contained 10 to 30 $\mu\text{g./cc.}$ at two hours after dosing and cerebrospinal fluid 0 to 2.5 $\mu\text{g./cc.}$ after the first and 3 to 4 $\mu\text{g./cc.}$ after the second 75 mg./kg. daily dosing. A dosage of 200 mg./kg. twice daily showed serum levels of 80, 120, 20 and 0 at six, eight, 12 and 24 hours respectively.

In mice following subcutaneous administration of 100 mg./kg. twice daily, the blood serum contained 11 $\mu\text{g./cc.}$ and urine 60 $\mu\text{g./cc.}$ Guinea pigs receiving perorally by cannula 750 mg./kg. showed 2.3 $\mu\text{g./cc.}$ of serum at two hours and none at four hours, and when given the same amounts subcutaneously in propylene glycol, the serum contained 7.8 $\mu\text{g./cc.}$ at 30 minutes, 10.1, 3.9, 2.3, and 2.2 $\mu\text{g./cc.}$ at two, eight, 16 and 24 hours respectively, indicating that chloramphenicol orally in guinea pigs is either poorly absorbed or rapidly degraded in the body.

Urinary Excretion

Urine was collected from dogs by catheterization, and from small animals in a metabolism cage. Chloramphenicol concentration in urine attained maximum levels at two to eight hours, depending

FIG. 4

Maximum serum levels occurred between two and six hours after oral administration and serum was negative in 12 to 24 hours. Chloramphenicol disappeared rapidly from serum on intravenous administration with negative findings at four to six hours.

upon mode of administration (Figure 5). Intravenous administration of single doses of 19 and 50 mg./kg. produced over 600 $\mu\text{g./cc.}$ of urine at two hours followed by gradual fall to 3 to 4 $\mu\text{g.}$ at 24 hours. Following oral single dose administration of 86 to 150 mg./kg. the urinary concentration reached a maximum of 1360 to 2500 $\mu\text{g./cc.}$ in four to six hours and 23 to 121 $\mu\text{g./cc.}$ at 24 hours. When given in oil suspension, a maximum concentration of 480 $\mu\text{g./cc.}$ was reached at eight hours and 7.5 $\mu\text{g./cc.}$ at 48 hours. Oral administration of two doses per day of 50 to 100 mg./kg. produced the first peak of 228 to 591 at two hours and the second peak at eight hours with 270

to 1300 $\mu\text{g./cc.}$, with 25 to 76 $\mu\text{g./cc.}$ at 24 hours. When given in propylene glycol, 41 mg./kg. twice daily intramuscularly, the two-hour averages for urinary concentration were 148 $\mu\text{g./cc.}$ and the 24-hour levels were 63 to 164 $\mu\text{g./cc.}$ (Table IV). The urinary excretion of chloramphenicol for a 24-hour period in dogs accounted for only 3.5 to 8.7 per cent of the total administered. Blood serum studies indicated absence of chloramphenicol in serum in four to six hours following intravenous and in 12 to 16 or 24 hours following oral or intramuscular administration, while urine contained considerable amounts at 24 hours, indicating absorption of Chloromycetin by tissues from

FIG. 5

High concentration of Chloromycetin occurred between two and 12 hours, peak at about eight hours, and the urinary excretion was prolonged over a 24-hour period.

TABLE IV
Urinary concentration of chloramphenicol in dogs

Number tests	Route	mg./kg. X daily	Hour intervals of sampling urine

* Second dose was administered at the end of the fourth hour.

which it is gradually liberated and excreted in the urine.

SUMMARY

1. Chloramphenicol (Chloromycetin) is moderately soluble (0.5 per cent) in water, urine and serum, propylene glycol (15 per cent), 50 per cent acetamide-water solution (5 per cent), and is insoluble in vegetable oils. Animal studies have indicated identical pharmacologic properties for material produced by fermentation and by chemical synthesis.

2. Chloramphenicol was readily absorbed following parenteral and oral administration and was found in blood serum, urine, bile and cerebrospinal fluid within two hours of administration.

3. It disappeared relatively rapidly from the blood stream, within four to six hours after intravenous and 12 to 16 hours after oral administration, with maximum blood serum concentration occurring between two and six hours and maximal urinary concentration between two and 12 hours. The urinary excretion persisted for over a 24-hour period with total recovery of 3.5 to 8.7 per cent.

4. Chloramphenicol was relatively non-toxic to animals and possessed no cumulative toxic effect on oral dosage of 100 to 200 mg. kg. per day to dogs for over a four-months period. The intravenous administration of 12.5, 25 and 50 mg. kg. was within the well-tolerated range. It caused no cumulative toxic effect on hemopoiesis, liver and kidney functions and visceral tissues. Blood pressure and respiration remained unaffected on

oral intake of 200 mg./kg. per day, and on intravenous administration to barbiturized dogs of 12.5 to 25 mg./kg. Gastro-intestinal reactions were uncommon, somatic reflexes, ocular and auditory functions remained undisturbed.

5. Lethal or near-lethal amounts of chloramphenicol orally and parenterally caused acute respiratory depression or failure, accompanied by fall of blood pressure and anoxia. Transient renal hematuria, probably of glomerular origin, and hydropic degeneration of glomerular capillaries occurred on administration of toxic amounts.

6. Intramuscular administration of oil suspensions or propylene glycol solution in doses of 0.5 to 1.0 gram caused considerable local tissue induration and necrosis, and a transient induration with 0.1 to 0.2 gram doses.

7. Oral administration of chloramphenicol to dogs provided measurable levels in the blood for about eight hours and in the urine for 24 hours.

SUSCEPTIBILITY OF MICRO-ORGANISMS TO CHLORAMPHENICOL (CHLOROMYCETIN)^{1,2}

By I. W. McLEAN, JR., J. L. SCHWAB, A. B. HILLEGAS, AND A. S. SCHLINGMAN³

(From the Research Laboratories, Parke, Davis & Co., Detroit 32, Mich.)

The antibiotic, chloramphenicol, produced by *Streptomyces venezuelae*, was originally reported by Ehrlich *et al.* (1, 2) and independently described by Carter, Gottlieb *et al.* (3, 4). Since these original reports the active principle has been chemically isolated and characterized (5, 6), synthesized (7) and is at present commercially available for clinical use.

Originally (1) activity was described against several Gram-negative bacteria, in particular *Shigella sonnei*, and against *Rickettsia prowazekii* in chick embryos. Smadel *et al.* (8-11) have notably extended this spectrum to include other rickettsial agents as well as two viruses, lymphogranuloma venereum and psittacosis. Smith *et al.* (12) reported that chloramphenicol was active, under the conditions tested, against Gram-negative bacteria, *R. prowazekii* and *Borellia recurrentis*; moderately active against Gram-positive bacteria and *Mycobacterium tuberculosis*; and inactive in the concentrations used against yeasts, filamentous fungi, protozoa and certain viruses. Youmans *et al.* (13) tested strains of virulent human-type *M. tuberculosis in vitro* and concluded that chloramphenicol was only moderately active when compared with streptomycin or para-amino salicylic acid.

Clinically, confirmation of laboratory activity has been obtained for certain of the rickettsial diseases (14-18), typhoid fever (19), brucellosis (20) and in urinary infections caused by certain Gram-negative bacteria (21). With the drug now available in quantity for clinical trial, it seems opportune at this time to collect the known informa-

tion with respect to the microbiological spectrum of this new chemotherapeutic agent.

METHODS

Viruses and Rickettsiae

Borrelia: Vaccinia virus (New York Public Health strain from Dr. S. K. Muckenfus, New York City Dept. of Public Health, N. Y., egg-adapted) was tested as a representative of this group of viruses. Two types of tests in chick embryos were used. The first consisted of mixing the chloramphenicol with the virus and inoculating 0.1 ml. of the mixture onto the chorioallantoic membrane of 10-day chick embryos. After four days incubation at 35° C. the membranes were examined and compared with controls for reduction in pock formation. The second method consisted of inoculating groups of treated, 10-day chick embryos *via* the yolk sac with a lethal dose of virus and repeating treatment on the following day by the same route. The eggs were candled twice daily and delay in death time and seven-day survivors recorded.

Erro: St. Louis encephalitis virus (egg-adapted from Dr. Carl Duffy, Wayne University, Detroit, Michigan, and a mouse-adapted laboratory strain) was tested to represent the group of virus encephalitides. Tests were conducted in embryonated eggs and mice. For the egg test, nine-day embryos were infected *via* the allantoic sac and treated 30 minutes before infection and on the 1st day after infection. The eggs were candled twice daily and time of death and seven-day survivors noted. In the mouse test, groups of 10 to 12 Gm. white Swiss mice were infected intracerebrally and treated intraperitoneally before infection and twice daily thereafter for 10 doses. Mean death time was compared with that of a control group.

Formido: The National Institutes of Health mouse-adapted strain of rabies virus was used, as well as a variant line of this strain adapted to the intramuscular route of infection. For the former, mice were injected intracerebrally with a lethal dose and daily treatments given intraperitoneally for four days. A similar procedure was used with the intramuscular strain except for the different route of virus administration. Time of paralysis and death of the treated mice was noted for comparison with control groups.

Legio: The anti-poliomyelitis virus tests were conducted by Drs. J. L. Melnick and E. R. Coorna (22) of the Yale University School of Medicine, New Haven, Conn. The Y-SK and Lansing strains (group 1) were used as well as Theller's intestinal virus of mice.

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

² Parke, Davis & Company trade-name.

³ Collaborators: F. A. Miller, J. S. Markey, A. Pucher, M. C. Galbraith, M. E. Dole, M. F. Sheehan, G. Coffey, J. M. McCracken, B. D. Moore, H. M. C. Manning. Research Laboratories, Parke, Davis & Company.

Rabula: The egg-adapted mumps virus tested was obtained from Dr. J. E. Smadel of the Army Medical School, Washington, D. C. The tests were conducted in seven-day embryonated eggs infected *via* the allantoic sac. Treatments were given 30 minutes before infection and on the second day. Allantoic fluid was harvested from each egg after seven-days incubation and tested for virus multiplication by the addition of washed chicken red blood cells. In addition a hemagglutination titration was performed on an aliquot pool of allantoic fluid from the groups of eggs. An untreated control group was included in the test for comparison of the number of positive eggs and level of group hemagglutinin titer.

Tarpeia: Tests against three strains of type A, seven strains of type A' and two strains of type B influenza virus have been conducted in 11-day chick embryos. The virus was inoculated into the allantoic sac and treatments given by the same route 30 minutes before infection and 60 minutes later. After 40 hours incubation at 35° C. the presence of infection in each egg and the hemagglutination titer of an aliquot pool of allantoic fluid were determined for each group as described above for mumps virus. Considerable work has been done using the mouse-adapted PR8 strain of type A in mice. In general, groups of 12 to 14 Gm. white Swiss mice were infected intranasally and treated by various routes and at different times with chloramphenicol. In the test reported here treatment was given intraperitoneally for seven days starting at the time of infection.

One inconclusive test has been made with the Green strain of distemper virus (commercial distemperoid, ferret-adapted) in ferrets. Two ferrets were infected intranasally and one was treated intraperitoneally at the time of infection and daily thereafter for three days. Severity of illness and time of development of fever were noted. The animals were sacrificed at the height of the disease; hence duration of illness could not be determined.

Tortor: Newcastle disease virus (California 14 from Dr. L. T. Giltner, Bureau of Animal Industry, Washington, D. C.) was tested in 11-day embryonated eggs and white Leghorn pullets. The test in eggs was conducted in the same manner as the influenza virus tests described above except that infection was determined by death or survival of the embryo. Comparisons of the average time of death of treated and untreated groups were made. In chickens the virus was administered intramuscularly and treatments were given approximately every 12 hours for four doses starting at the time of infection. Time of the appearance of symptoms and number of survivors compared with a control group were noted.

The chick bronchitis virus (obtained from Dr. C. H. Cunningham, Michigan State College, East Lansing, Michigan) was tested in chick embryos as described above for Newcastle disease.

Laryngo-tracheitis virus (commercial vaccine strain) was tested on the membrane of chick embryos using the technique described for vaccinia virus.

Rickettsia: Considerable work has been done with epidemic typhus (*R. prowazekii*, Breinl strain) in chick

embryos. In the work reported here, groups of six-day chick embryos were infected *via* the yolk sac and treated once on the third day after infection by the same route. Average time of death and number of survivors were compared with an untreated control group.

The results with murine typhus (*R. typhi*), scrub typhus (*R. tsutsugamushi*) and rickettsialpox (*R. akari*) were taken from the work of Smadel *et al.* (8-11). Using the method described above, their findings for murine typhus in eggs have been confirmed in this laboratory.

Dermacentroxenus, Coxiella and Miyagawanella: The reports of Smadel *et al.* (8-11) are included in the table for Rocky Mountain spotted fever (*D. rickettsi*), Q fever (*C. burnetii*), lymphogranuloma venereum (*M. lymphogranulomatis*) and psittacosis (*M. psittacii*).

Bacteria

The bacterial species reported here were tested for their susceptibility to chloramphenicol by inoculating a specified dilution or quantity of liquid culture into media containing varying concentrations of the drug, the end point being taken as the lowest concentration which caused complete inhibition of growth for 18 hours. Except as indicated the original transplants for preparation of suspensions were made from cultures dried from the frozen state.

The aerobes were tested by adding 1.0 ml. of a standardized dilution of a tryptose broth culture to 1.0 ml. quantities of tryptose broth containing varying concentration of chloramphenicol. The final concentrations used varied from 0.1 to 200 µg/ml. The tubes were incubated for 18 hours and the results recorded as "growth" or "no growth."

It was necessary to utilize special media for some of the more fastidious organisms. However, the same technique was used, replacing the tryptose broth with the special medium required. *Brucella abortus* was grown under 10 per cent CO₂ for 48 hours (No. 1335).

The anaerobes were tested by adding varying concentrations (ranging from 0.1 to 500 µg/ml.) of chloramphenicol to melted agar medium cooled to 40° C. To each tube, 0.1 ml. of a 24-hour liquid culture of the organism to be tested was added. The tubes were then shaken thoroughly and allowed to gel. Growth was recorded as positive or negative after 24 hours incubation.

Beef infusion agar (2 per cent) containing 2 per cent glucose (pH 8.2) was used for *Clostridium perfringens*, *novyi* and *septicum*. *Cl. fesceri* was tested in 2 per cent liver infusion agar (pH 8.2) and the anaerobic agar recommended by Records and Vawter (23) was utilized for *Cl. hemolyticum*. *Cl. tetani* was grown in Taylor medium containing 0.5 per cent agar and incubated in an atmosphere of hydrogen and carbon dioxide.

Fungi

In determining the susceptibility of fungi to chloramphenicol, a broth dilution method was employed. Serial dilutions of the drug in broth were dispensed in 1 ml. amounts in Wassermann tubes and to each tube was added

1 ml. of inoculum in broth. The tubes were incubated at 30° C. for one to seven days, depending upon the species, and then observed for inhibition of growth. The minimum concentration of the drug causing complete inhibition of growth was taken as the end point.

Modified Sabouraud's broth (dextrose 2 per cent, neo peptone 1 per cent) was used in preparing the dilutions of the drug and the fungus suspensions. In the case of the actinomycetes, Brain-Heart Infusion Broth (Difco) was employed.

Three types of inocula were used. 1) Spore suspension: In heavily sporulating species suspensions were prepared from either agar slant or agar plate cultures of the fungus. In the case of agar slants, broth was

added to the tube, the fungus stirred up with an inoculating needle and the tube then shaken. When using agar plate cultures the mycelium was scraped from the surface of the plate, placed in broth and shaken. The suspensions were then filtered through cotton and the spores counted on the hemocytometer. 2) Spores and mycelial fragments: Species having limited sporulation were removed from the surface of the culture medium, emulsified with broth either in a Waring Blender, by shaking with glass beads or by grinding in a mortar. The suspension was filtered through a loose cotton mat and in some instances the number of fragments and spores per ml. was determined by means of the hemocytometer. 3) Mycelial suspension: The mycelium of non-sporulating species was

processed in the manner described for preparing the suspension of spores and mycelial fragments.

All of the fungi were tested first in a series of dilutions ranging from 50 to 1000 µg/ml. of the drug. The actinomyces, *Actinomyces bovis* and *Nocardia asteroides*, were retested at lower concentrations and four species, *Trichophyton interdigitale*, *T. mentagrophytes*, *T. rubrum* and *Microsporum canis*, at higher concentrations (up to 2500 µg/ml.) of chloramphenicol. In order to keep the drug in solution at the higher concentrations 1.8 ml. of the drug-broth mixture and 0.2 ml. of inoculum were used in each tube instead of 1 ml. of each as in the lower concentration series.

Spirochetes and Protozoa

The authors are indebted to Dr. Paul E. Thompson (24) and Dr. O. M. Gruhitz (25) of the Parke, Davis Research Laboratories for the data included in this section.

In Vitro Tests: *Endamoeba histolytica* (University of Chicago strain, with mixed bacterial flora) was tested in two media, Egg-Locke diphasic and Balamuth (essentially protein free). Various concentrations of chloramphenicol were incorporated in these media and amebicidal activity determined by microscopic examination for motility after 24 hours at 37° C.

Borrelia novyi and *recurrentis* and *Trichomonas foetus*

§ Mycelial fragments counted.

were suspended in a suitable menstruum containing varying concentrations of chloramphenicol, as indicated in Table IV, and observed for immobilization. Observations were made after two hours in the case of the *Borreliae* and after seven hours exposure for trichomonas.

In Vivo Tests: *Plasmodium lophurae* was tested in ducks (intraperitoneal treatment) and chicks (oral treatment) and the results compared with the activity of quinine.

Rats and dogs were used to evaluate the activity of chloramphenicol against *E. histolytica* *in vivo*. Treatment was given orally and results expressed as number of animals cleared of infection or degree of suppression of infection.

B. novyi was tested in groups of mice treated by either the intraperitoneal or oral route. Results are expressed as percentage suppression of spirochetemia.

Rabbits infected with *Treponema pallidum* were treated with various concentrations of chloramphenicol twice daily for eight days. Rate of disappearance of treponemes and degree of healing of lesions under treatment were noted. The animals were held to check for relapses in the dosages at which healing under treatment was noted.

RESULTS

Tables I to IV summarize the results obtained with the different micro-organisms that have been tested in the laboratory. Wherever possible the minimal inhibiting concentration of chloramphenicol for the strain, under the conditions tested, is given. Otherwise, the maximum concentration tested or the dose administered, in the case of *in vivo* tests, is entered. The identifying numbers given for the bacteria and fungi are those assigned by the Parke, Davis and Company culture bureau, where a complete history of the strain is available. Strains without assigned numbers are for the most part recent isolates from clinical cases prior to or during treatment with chloramphenicol.

The Emergence of Microbial Resistance

With the finding of considerable variation in susceptibility to chloramphenicol of different cultural lines of certain bacterial species, it became

<i>Alcaligenes metalcaligenes</i>	clinical case	7	1250	2250

of interest to determine whether increased resistance to chloramphenicol could be induced by laboratory manipulation. Our early observations indicate that certain species of micro-organisms will develop resistance to chloramphenicol when sub-inoculated on media containing increasing concentrations of the drug. The bacterial species tested include *Salmonella typhosa*, *Aerobacter aerogenes*, *Escherichia coli*, *Proteus* sp., *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, and *Alcaligenes metalcaligenes*.

The test was carried out by sub-inoculating 0.1 ml. of the various cultures into Brain-Heart Infusion Broth (Difco) with 10 per cent horse serum added and containing various concentrations of chloramphenicol. The cultures were incubated for 72-96 hours. From the tube containing the highest concentration of chloramphenicol, in which good growth was obtained, 0.1 ml. was sub-inoculated into 2.0 ml. of medium containing the same and higher concentrations of the drug. In Table V the preliminary results of this study are indicated. It can be seen that the susceptibility of these organisms has decreased from approximately 2 to 50 fold in the course of these passages.

The results of tests designed to detect a similar phenomenon for *Rickettsia prowazekii* have so far been negative. One series has been carried through 13 passages, and a second through six passages in chick embryos treated with partially inhibiting doses of chloramphenicol. Comparative tests of the passaged and stock strains have indicated no change in susceptibility to the drug under these conditions.

SUMMARY AND CONCLUSIONS

Sixty-four genera of micro-organisms including 290 species and strains have been tested for their susceptibility to chloramphenicol. The results are recorded in Tables I to IV.

From Table I it appears that all of the *Rickettsiae* tested are susceptible to chloramphenicol. *Coxiella burnetii* (Q Fever) may be more resistant than the others as larger doses are required to produce corresponding delay in mean death time of treated embryos. Possibly the whole lymphogranuloma venereum-psittacosis group of virus (*Miyagawanella*) will prove to be as susceptible as the type species. There are indications that influenza virus in mice and the virus of Newcastle disease of chickens respond somewhat to comparatively massive doses of the drug. It is possible, however, that the therapeutic effect seen can be explained by the action of the drug upon secondary bacterial invaders. While this hypothesis is apparently borne out by the negative results with chloramphenicol on these viruses in embryonated eggs, further work and possibly controlled clinical trials are indicated.

Tests against the virus of poliomyelitis have proved negative. Dr. J. L. Melnick states as follows: "I have gone over the records of the work done with Dr. Filiberto Ramirez Corria on the use of this material on two strains (Lansing and Y-Sk) of poliomyelitis virus and on Theiler's intestinal virus of mice. When the viruses were titrated using saturated aqueous solutions of Chloromycetin as diluent, there was no effect on the titer even when the viruses were inoculated into mice receiving daily inoculations of the drug (1 cc. of saturated solution intraperitoneally). Further-

more, daily oral administration of Chloromycetin did not appear to have any effect on the intestinal carrier state² of mice spontaneously harboring Theiler's virus of mouse encephalomyelitis" (22).

From Table II, which gives the results from tests of over 200 bacterial strains representing 25 genera, it can be concluded that considerable variation in susceptibility is encountered between genera as well as between species and even strains within the species. Under the conditions tested susceptibility to concentrations of 10 $\mu\text{g}/\text{ml}$. or less, indicating possible clinical application, was observed for 21 of the genera. These include *Aerobacter* (2/2),⁴ *Bacillus* (6/6), *Brucella* (7/7), *Corynebacterium* (3/3), *Diplococcus* (3/3), *Escherichia* (11/11), *Hemophilus* (7/7), *Klebsiella* (11/12), *Micrococcus* (19/19), *Neisseria* (4/4), *Pasteurella* (8/8), *Proteus* (8/10), *Pseudomonas* (1/19), *Salmonella* (37/37), *Sarcina* (3/3), *Shigella* (16/16), *Streptococcus* (8/8) and *Vibrio* (1/1). *Pseudomonas*, though fairly resistant, is included since it seems to be susceptible to chloramphenicol in concentrations obtainable in the urine. The results given for *Alcaligenes* leave the status of this genus somewhat in doubt. A stock strain of *A. faecalis* was found to be susceptible but three different isolates from the same clinical case of *A. metalcaligenes* infection were found to be highly resistant. A somewhat similar situation is observed for *Proteus vulgaris* where two of ten strains tested required a somewhat higher concentration (25 $\mu\text{g}/\text{ml}$.) for complete inhibition. An interesting finding was encountered with the *Clostridia*. While this group in general was of very low susceptibility, one strain, the Mueller variant of *Cl. tetani*, was very susceptible. This variant does not produce spores in culture, which raises the speculation that possibly the apparent resistance of this group is a reflection of the resistance of the spores rather than of the vegetative forms.

While not within the scope of this paper, *in vivo* laboratory trials with certain of the bacterial agents have been conducted. Gould *et al.* (26) report encouraging results with the cholera vibrio in mice and Gruhzit (25) has found activity in mice

against certain of the Gram-positive cocci and the salmonella group. Sarber (27) has treated mice infected with *Hemophilus pertussis* and found chloramphenicol to be an effective chemotherapeutic agent. Clinical trials are in progress against many of these pathogens. To date clinical confirmation has been obtained in typhoid fever (19), brucellosis (20), and certain urinary infections caused by Gram-negative species (21).

Of the forty species or strains of fungi tested for susceptibility to chloramphenicol, Table III, only two were completely inhibited by the drug at the concentrations used in the test. These two species, *Actinomyces bovis* and *Nocardia asteroides*, both of which belong to the actinomycetes, were inhibited by 5 $\mu\text{g}/\text{ml}$. and 20 $\mu\text{g}/\text{ml}$. of the drug, respectively. Since blood levels of this magnitude are easily attained, trial on clinical infections with these agents is indicated.

Growth of four species of ringworm fungi, *Trichophyton mentagrophytes*, *T. interdigitale*, *T. rubrum* and *Microsporum canis*, was retarded by 1000 $\mu\text{g}/\text{ml}$. of the drug but complete inhibition could not be obtained even when the drug concentration was increased to 2500 $\mu\text{g}/\text{ml}$.

With the possible exception of the spirochete of relapsing fever (*Borrelia recurrentis*), the results with the spirochetes and protozoa tested were not promising. Doses of 12.5 mg/Kg. twice daily for eight days were ineffective on syphilitic lesions in rabbits. Although similar treatment with 25 or 50 mg/Kg. cleared the lesions, relapses occurred when treatment was stopped.

Attempts to induce increased resistance to chloramphenicol by passage in the presence of the drug have been successful in the case of seven bacterial species, but not for *R. prowazekii* in the embryonated egg. It remains to be seen whether, under practical conditions in the clinic, this finding will be of importance.

PRELIMINARY REPORT ON THE USE OF CHLORAMPHENICOL (CHLOROMYCETIN) IN THE TREATMENT OF ACUTE GONORRHEAL URETHRITIS¹

By J. E. SMADEL, C. A. BAILEY, AND D. S. MANKIKAR

(From the Army Medical Department Research and Graduate School, the Commission on Immunization of the Army Epidemiological Board, Washington, D. C., and the Institute for Medical Research, Kuala Lumpur, Malaya)

The great advances which have been made in recent years in the treatment of gonorrheal infections would appear to have provided the medical profession with adequate therapeutic agents for this disease. The numerous advantages of penicillin treatment have resulted in its replacing the sulfonamide drugs, except in selected cases (1). Even the disadvantages of parenteral injections of penicillin have been avoided by a number of workers who have administered the antibiotic by mouth (1). Indeed, Campbell, Dougherty and Curtis reported on the oral use of penicillin in the prophylaxis of gonorrhea at an earlier session of this Symposium (2). Despite the fact that penicillin has many attributes of an ideal drug for the treatment of gonorrhea, it has one distinct drawback, *i.e.*, its suppressive effect on a coexisting syphilitic infection. This problem of the possible masking of syphilis by treating acute gonorrhea patients with amounts of penicillin which are adequate for the bacterial infection but inadequate for the spirochetal infection is of tremendous importance (1, 3). Therefore, the search must continue for a drug with the activity of penicillin against the gonococcus but without its marked anti-spirochetal action. This report is a progress note which presents certain preliminary data suggesting that chloramphenicol, or Chloromycetin,² approaches penicillin in its efficacy in the treatment of acute gonorrheal urethritis in the male and that this new drug is distinctly less spirocheticidal than penicillin.

During the past three months in Malaya we have used Chloromycetin in treating 45 men with gonorrhea. Thirty-four of these received the synthetic type of drug and 11 the fermentation type. Data on 32 patients in this series are summarized in Table I. Each person had a purulent urethral discharge when admitted to the study. This had been present for three days or less in the majority of instances, but three individuals in the group had suffered for 21, 28, and 60 days, respectively. The mean duration of disease when therapy was begun was from four to 12 days in the four subgroups listed in Table I. Smears of the exudate taken from each patient

TABLE I
Chloromycetin in the treatment of 32 males with acute gonorrheal urethritis

	Chloromycetin dosage			
	Synthetic		Fermentation	
	3.0-3.5 grams	1.0-1.5 grams	3.0-3.5 grams	1.0-1.5 grams
Number of cases	11	10	6	5

Range	5-72	24-72	7-96	18-60

on admission contained numerous Gram-negative intracellular diplococci. Furthermore, cultures, made on Harrison's agar, yielded *N. gonococci* from all but one of the cases; the single exception suffered a relapse on the eighth day and is included because of this.

Each of the patients was treated with a single oral dose of one or the other type of Chloromycetin and permitted to continue his normal occupational duty. Slightly more than half the patients listed in the table received a total of 3.0 or 3.5 grams and the remainder were given 1.0 or 1.5 grams. It is apparent from the tabular data that similar results were obtained as regards disappearance of urethral discharge in the four subgroups, *i.e.*, patients who received the smaller or larger dose of either the synthetic or fermentation type of drug. Later on

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

² Trade name of Parke, Davis and Company. The Chloromycetin used in the present work was supplied by Parke, Davis and Company. Lots of drug produced by the fermentation and by the synthetic process were made available.

additional comments will be made on other patients not mentioned in the table who were treated with the smaller doses of drug.

Within 24 hours after the therapeutic dose had been given the urethral discharge had disappeared in 13 of the 32 patients. Furthermore, in another 17 of the group the discharge was reduced to a drop or so of thin watery material which was obtained by stripping. Two of the 32 persons still yielded a drop of purulent exudate at this time. Stained smears of the 19 exudates revealed that only one had Gram-negative intracellular diplococci; the culture of this material failed to yield *N. gonococci*. However, a few colonies of *N. gonococci* were grown from a thin milky exudate of another patient who was cultured 24 hours after being given 3.0 grams of drug. Furthermore, the material from three other patients taken at this time yielded colonies resembling *N. gonococci*.

On the third to fifth days after treatment was given, 30 of the 32 patients were subjected to prostatic massage. Materials for smear and culture were obtained from 18 of these. In no instance were Gram-negative intracellular diplococci found microscopically; indeed, even leukocytes were recorded as being absent from the smears of 12 of the specimens. Seventeen of the 18 cultures of prostatic secretion taken during this period contained no *N. gonococci* but from one secretion a few colonies were grown which resembled gonococci morphologically. Three subsequent massages of Patient 4, who had supplied this questionable material, were non-productive and he has now remained well for eight weeks.

A total of four relapses have been noted to date among the 32 patients who have been tabulated. One occurred 28 days after treatment with 3.0 grams of synthetic drug, which was 26 days after complete disappearance of all signs of disease. This individual had been re-exposed recently and he may represent a reinfection. Two patients relapsed on the 19th and eighth days, respectively, after treatment with 3.0 grams of synthetic drug; discharges of both had initially cleared within 48 hours and recurred following inebriation. The fourth case was apparently cured within 36 hours after receiving 1.0 gram of fermentation drug but relapsed on the 14th day. Each of these four patients was again treated with a single dose of 3.0 grams of Chloromycetin and responded well.

Three additional patients not included in the table are worthy of mention. Each received a single dose of 1.0 or 1.5 grams of Chloromycetin but was subsequently given an additional 3.0-gram dose one to four days later. This additional medication appeared indicated because of the persistence of some discharge, or the presence of Gram-negative intracellular diplococci. However, none of the cultures taken at the time the supplementary drug was administered were later found to contain gonococci. Each of the three patients recovered promptly after being given the additional drug. Thus, it appears that the administration of 1.0 gram or 1.5 grams of drug in a single dose may provide inadequate therapy in a proportion of cases.

Smith and his coworkers (4) found that rabbits which had been infected with the Nichols strain of *Treponema pallidum* and then treated with Chloromycetin for eight days at the rate of 25 mg. per kilo per day showed no change in their lesions nor did the spirochetes disappear. They also noted that daily doses of 50 and 100 mg. per kilo cleared the lesions of spirochetes but that the effect was temporary.

Our experience with Chloromycetin in two patients with primary chancres suggests that the results in man may be similar to those just mentioned in rabbits. Dark field examination of fluid from the lesion of one man showed an average of three motile spirochetes per field. The patient received 4.0 grams of Chloromycetin in a single dose (45 mg. per kilo of body weight) and repeated examinations over the next 18 hours revealed the same number of active treponema. He was then given 3.0 grams of drug at one time followed by five doses of 0.5 gram each at three-hour intervals, thus totaling 5.5 grams (62 mg. per kilo) over this 18-hour period. At the end of this time two spirochetes of reduced motility were found in the three preparations examined and eight hours later only one non-motile organism was seen in two samples. During the succeeding week the chancre healed slowly and spirochetes were not observed. The second patient was given an initial dose of 70 mg. per kilo of body weight and an additional 58 mg. per kilo over the next 15 hours. Seventeen hours after treatment was started motile spirochetes could no longer be found but there was

no evidence of healing of the chancre during the succeeding three days.

CONCLUSIONS

The present information, although preliminary, indicates that Chloromycetin is of some value in the treatment of acute gonorrheal urethritis in the male. Single oral doses have been employed almost exclusively in these studies; the efficacy of the same total amounts of drug given in divided doses over a period of one or two days should be investigated.

Chloromycetin is appreciably less effective than penicillin against *Treponema pallidum*. Since an agent capable of controlling gonorrhea without masking syphilitic infection is to be desired, further studies of the use of Chloromycetin in the treatment of venereal disease are indicated.

ADDENDUM

Since the above was submitted additional cases have been added to this series and supplementary data obtained on the original patients. One lot of chloramphenicol, presumed to be fermentation type, later proved to be synthetic; this necessitated minor changes in the tabulation of the data. A total of 48 patients with acute gonorrheal urethritis have been treated with chloramphenicol. Of these, 42 were given synthetic drug in a single oral dose. Twenty-four were given 3.0 to 3.5 grams and 18 were given 1.0 to 1.5 grams. The remaining six received 3.0 to 3.5 grams of fermentation drug. The mean duration of disease in these three sub-groups prior to treatment was 8, 4, and 11 days, respectively. The clinical response was essentially the same in each sub-group; therefore, neither the type of drug nor the dosage employed appeared to affect the results. Dysuria disappeared within 36 hours (average for the 48 patients) and discharge (as determined by the absence of exudate on stripping) within 49 hours. Smears of the discharge with few exceptions were free of gonococci by the next day and leukocytes generally were absent from the discharge in those instances where this sign persisted longer than 48 hours. Ten patients or 20 per cent of this entire series had relapses during the month following treatment. There was no apparent difference in the number of recur-

rences in the three sub-groups. All relapses were treated with a single oral 3.0 gram dose of chloramphenicol and responded satisfactorily.

The primary lesion of the first patient with a syphilitic chancre mentioned in the text, who received 9.5 grams of chloramphenicol over a two-day period, healed completely by the tenth day after beginning treatment. During the fourth week a chancre containing spirochetes reappeared at the site of the original lesion. The patient was then retreated, receiving three single 1.0 gram oral doses of synthetic drug at daily intervals. Spirochetes disappeared from the recurrent chancre the day following the third dose of drug and the lesion was completely healed nine days later. On the 44th day after the first appearance of the chancre and the 36th day after initial treatment, a Kahn test gave a plus-minus reaction; it had been consistently negative previously. The three chancres of the second patient, who received 5.5 grams during 18 hours, healed by the 12th day but 30 days later a fresh chancre reappeared at one of the original sites. The Kahn reaction of the second patient remained negative throughout the 35 days of observation following the original appearance of the lesions.

Nine patients with acute gonorrheal urethritis were treated with single oral doses of 3.0 to 4.25 grams of aureomycin. In this small series the clinical effect was essentially similar to that obtained with chloramphenicol and the results were somewhat better than those obtained by Collins *et al.* (5). This may be due to our use of larger amounts of drug. The mean duration of disease before treatment in this series was 15 days. Dysuria and discharge disappeared on the average in 29 and 82 hours, respectively. In all cases smears were negative for gonococci by the day after treatment. These patients were followed for an average of 28 days during which time there were no relapses.

THE BENEFICIAL EFFECT OF CHLOROMYCETIN IN BRUCELLOSIS^{1, 2}

By THEODORE E. WOODWARD,³ JOSEPH E. SMADEL,⁴ WILLIAM A.
HOLBROOK,⁵ AND WILLIAM T. RABY⁶

(From the Department of Medicine, University of Maryland School of Medicine, and the
Department of Virus and Rickettsial Diseases, Army Medical Depart-
ment Research and Graduate School)

Newer antibiotic agents have greatly extended the range of specific therapy in the group of infectious diseases with increasing rapidity. Much of this effort is directed against gram-negative bacilli in which group the Brucellae command a prominent position. Up to the present time the use of therapeutic agents in brucellosis has resulted in a certain measure of success, but with limitations, particularly from the point of view of failure to prevent recurrences.

One of these new antibiotics is chloramphenicol (Chloromycetin) a streptomycetes, first isolated by Burkholder,⁷ crystallized by Ehrlich and his associates (1) and demonstrated to possess potent antimicrobial effect against many gram-negative organisms including all members of the Brucella group (2). The pharmacological and toxicological characteristics of this new agent are now a matter of record (2) and the chemical structure of the antibiotic agent is known (3). In experimental and clinical infections the synthetic form of Chloromycetin has been found comparable to the naturally produced product in degree of effectiveness (4).

Chloromycetin is well absorbed from the gastrointestinal tract. Serum levels of the drug after oral administration have been found comparable to those obtained by parenteral administration.

⁶ Resident in Medicine.

⁷ Dr. Paul R. Burkholder, Osborn Botanical Laboratory, Yale University.

There are no reports up to the present time of toxic manifestations resulting from the oral administration of Chloromycetin. The prolonged intramuscular administration in dogs resulted in a moderately severe anemia without significant changes in the white blood cells and without disturbance in hepatic or renal functions (2).

The initial studies of the antibiotic spectrum of Chloromycetin *in vitro* and *in vivo* in animals indicates a wide range of usefulness, particularly in rickettsial and gram-negative infections (2, 5). Among the gram-negative organisms showing a considerable degree of sensitivity to this antibiotic are *Brucella abortus*, *Brucella melitensis* and *Brucella suis*. It is interesting to point out that up to the present time Chloromycetin has not failed to exert great beneficial effect in those clinical diseases whose organism has been found sensitive to the agent when tested in the laboratory.

In Maryland the opportunity to treat brucellosis afforded itself because of a rather prevalent incidence of the *B. abortus* and *B. suis* types of infection. We have observed nine patients with active infection during the period from July, 1948, to February, 1949. Six of these patients were experiencing an initial attack, whereas three patients showed a relapse of fever two, three and five months after the primary illness treated with a combined course of streptomycin and sulfadiazine. The present study deals with the results obtained following Chloromycetin administration in these nine patients. Observations on non-treated cases (controls) were not made because of the insufficient number of available patients.

METHODS AND PROCEDURE

Chloromycetin was administered orally, the antibiotic having been furnished by Parke, Davis and Company in the form of 0.25 gm. tablets and capsules. The tablets were swallowed whole and in spite of the bitter taste no difficulty was experienced with oral administration. Chlo-

romycetin now supplied in gelatin capsules is taken orally without unpleasantness.

The dosage regimen adopted for this study was empirical and based, in general, on prior experience in scrub typhus and typhoid fever (6, 7). The large initial dose in each instance was approximately 50 mg. per kilo. After the initial dose, Chloromycetin was given at three hour intervals in 0.25 gm. amounts until the temperature was normal and for a minimum of five days thereafter.

Blood levels for Chloromycetin were determined throughout the period of treatment. A modification of the method of Joslyn and Galbraith (8) which employs inhibition of growth of *Shigella sonnei* was used for these micro-biological assays. The sensitivity of the brucella was determined by inoculating a standard quantity of the bacterial suspension into serial dilutions of Chloromycetin in tryptocase broth. After approximately three days' incubation, the sensitivity was determined turbidimetrically by the 50 per cent end-point technique as applied to fluid culture.

Confirmation of the clinical diagnosis of brucellosis was sought in each instance through the following procedures: (1) Blood was taken from the patient for culture before instituting treatment. Venous blood was inoculated directly into tryptocase broth which was then incubated at a temperature of 37° C. in an atmosphere of 10 per cent carbon dioxide. Subcultures were made on tryptocase agar utilizing the same conditions. Blood cultures were repeated on each patient at least three times during the period of hospitalization and one month following discharge from the hospital when the first follow-up studies were performed. (2) Agglutination tests, utilizing *B. abortus* as antigen, were performed by the usual clinical laboratory techniques.

Hemoglobin levels, red and white blood cell counts and differential leukocyte counts were performed in the usual manner.

RESULTS

a. Confirmation of diagnosis: In seven of the nine patients constituting this series of treated pa-

tients, four showed a positive blood culture for *B. abortus*, two for *B. suis* and one for *B. melitensis* prior to the administration of Chloromycetin. All of the post-treatment blood cultures remained sterile. In all nine patients a significantly high rising titer for brucella agglutinins was demonstrated (Table I).

b. Blood levels of Chloromycetin and sensitivity tests: The levels of Chloromycetin in the blood were found to be comparable to those obtained and reported elsewhere (9). For 24 hours following the initial dose of the antibiotic, the level ranged in seven patients tested from 10 to 50 gamma per cc. During the ensuing therapeutic days when the patients were on a comparable dose of .25 gm. every three hours the average level was 15 gamma per cc. up to the time of cessation of therapy. The sensitivity of the infecting organisms tested on four patients ranged from .78 to 2.4 gamma per cc. (Table I). These concentrations compare favorably with the figures reported by Smith *et al.* (2) who had previously demonstrated inhibition of Brucellae to Chloromycetin in the following concentrations: *B. abortus*, 2.0 gamma per cc.; *B. suis* and *B. melitensis*, 0.5 gamma per cc.

The course of undulant fever in patients treated with Chloromycetin

The mean duration of fever prior to treatment in the nine treated patients was 30 days. Two of these patients were more seriously ill than the others. Within 36 hours after the start of specific treatment they were resting more comfortably, spent a more restful night for the first time since

TABLE I
Tabulation of results on the use of Chloromycetin in brucellosis

Mean			30.3	2.7	33.0		83	20.25					

the onset of illness and diaphoresis was greatly reduced. In the seven other patients there seemed to be immediate improvement of the body and joint pain and there was decidedly improved taste for food.

The mean in the nine patients for duration of fever after beginning Chloromycetin treatment was 2.7 days. The temperature in all remained normal thereafter. Seven of the nine patients had enlarged spleens felt from one to three fingers below the costal margin. In five patients the spleen was observed to become non-palpable during the course of antibiotic treatment and in the remaining two the spleen disappeared to palpation several days after stopping the drug. The response to treatment in six patients is best demonstrated in figures 1-6 which are accompanied by brief clinical records.

Occurrence of complications

a. Relapses: There was one relapse, the recurrence beginning 31 days following discontinuance of Chloromycetin. Although we were unsuccessful in re-isolating the *B. abortus* from the blood, it is of considerable importance that the re-

administration of Chloromycetin resulted in a prompt clinical response.

b. Complications: In the group constituting this series of nine treated patients there were no complications attributed to brucellosis observed after Chloromycetin treatment. The patient with the melitensis type infection developed an orchitis three months following sulfadiazine and streptomycin treatment. Two days after receiving Chloromycetin the patient noted a definite improvement not only in reduction in size of the testicle but a marked reduction in tenderness.

Illustrative Case Reports

Case No. 1. (Figure 1.) The patient was a 27-year-old Negro who contracted illness from drinking raw milk. He was hospitalized at Fort Meade on the 29th day of disease. His early complaints were primarily those of fever, profuse sweating, headache, anorexia, general weakness, and malaise. After admission the evening temperature reached 105° F. and ranged from 102 to 105° prior to the administration of specific therapy. His nights were restless because of the pyrexia, sweating and general aching. There were no signs of a localized infection. On the 32nd day of illness culture of the blood was positive for *B. abortus*. The organism isolated was sensi-

FIG. 1. (CASE NO. 1.) CHART OF RESULTS IN A PATIENT (MALE, AGE 27, 160 LBS.) WITH BRUCELLOSIS OF ABORTUS TYPE—TREATMENT WITH CHLOROMYCETIN

FIG. 2. (CASE No. 3.) THE COURSE OF ILLNESS IN A PATIENT (MALE, AGE 32, 160 LBS.) WITH BRUCELLOSIS OF SUIIS TYPE—TREATMENT WITH CHLOROMYCETIN

tive to Chloromycetin in the concentration of 2.4 gamma per cc. At this time the serum agglutination for *B. abortus* was 1/2560. The spleen was readily palpable and there were scattered rales throughout both lungs. Chloromycetin was given orally with an initial dose of 3.0 gms. and a subsequent dosage of .25 gm. every three hours. The drug was well tolerated. On the first night of drug treatment the patient was more comfortable and diaphoresis was greatly reduced. On the following day the appetite was decidedly improved and the bedside appearance was brighter. The evening temperature reached normal 48 hours after institution of treatment and remained normal thereafter. The spleen could not be felt after five days of therapy. A total of 15.75 gms. of Chloromycetin was administered, the course extending until five days of normal temperature. Three blood cultures taken during the convalescent period were sterile. The patient was discharged 25 days after the institution of Chloromycetin and now remains free of symptoms.

Case No. 3. (Figure 2.) A 32-year-old white man first became ill in June, 1948, with evening fever, anorexia, general malaise, weakness and chilly sensations. For one year the patient had been employed in a slaughter house participating in the slaughtering of cattle, hogs and in the packing of meat. For the initial attack he received combined streptomycin and sulfadiazine. At this time the spleen was enlarged, firm and smooth to palpation and descended two finger breadths below the costal margin. The agglutinins for *B. abortus* rose from 1/1280 to 1/10,240. The temperature became normal after seven days of this combined treatment but the spleen did not

appreciably change in size. Two months later the patient noticed a recurrence of symptoms, the evening temperature reached 104° F. and the spleen was readily palpable. The serum agglutination titer was 1/1280 and the blood culture was positive for *B. suis*. Chloromycetin was administered with an initial dose of 50 mg. per kilo. beginning on the 10th day of relapse. The drug was then administered orally in .25 gm. amounts every three hours until five days of normal temperature. The evening temperature reached normal 2.5 days following the institution of treatment, at which time the patient was asymptomatic. In six weeks the patient had no complaints, the blood cultures were sterile and the spleen was not palpable. The patient is now eight months convalescent and apparently well.

Case No. 4. (Figure 3.) A 28-year-old male contracted *B. suis* infection from handling meat in a city packing establishment. The primary attack began in June, 1948, at which time the blood culture revealed *B. suis*. The spleen was palpable on this admission. The evening temperature averaged 101°, and the patient complained primarily of general muscular aching along with sweating and anorexia. After three weeks of temperature a combined course of streptomycin and sulfadiazine was administered. The temperature reached normal in seven days, and the patient was generally improved. Brucellin was employed during the convalescent period which was accompanied by body pain and fever soon after administration. A persistent daily fever reappeared less than two months after the first therapeutic course. The blood revealed *B. suis* and the serum agglutinating titer

FIG. 3. (CASE No. 4.) CHART OF RESULTS IN A PATIENT (MALE, AGE 28, 155 LBS.) WITH BRUCELLOSIS, SUIS TYPE—TREATMENT WITH CHLOROMYCETIN
No recurrence after eight months.

FIG. 4. (CASE No. 5.) THE RESPONSE TO CHLOROMYCETIN IN A PATIENT (MALE, AGE 29, 120 LBS.) SEVERELY ILL WITH BRUCELLOSIS (ABORTUS TYPE)
No recurrence after six months.

The appetite improved and sweating was lessened after two days of therapy. The spleen was not palpable on the sixth post-treatment day. The total amount of Chloromycetin used was 24.75 gms. Blood taken for culture on the second, fifth, sixth and 16th post-treatment days was sterile. The highest agglutinating titer for *B. abortus* was 1/1280. Follow-up examination six weeks after discharge from the hospital revealed an afebrile patient without complaints. At the time of this examination the spleen was not palpable and the blood culture was sterile.

Case No. 7. (Figure 6.) The patient, a 24-year-old white man, acquired an abortus type of brucellosis from the butchering and sampling of meat. A prodromal period of several weeks was characterized by a profound lethargy and aching of the head and back. Fever was first observed several weeks later on about January 1, 1949, with the evening temperature reaching 101° F. Several days prior to hospitalization diaphoresis was pronounced and the temperature reached 104° F. All symptoms were then accentuated, and nausea with vomiting occurred. Blood taken prior to the institution of specific treatment revealed a gram-negative organism identified as *B. abortus*. The agglutinating titer at this time was 1/1280. On the 32nd day of fever Chloromycetin was administered with an initial dose of 3.0 gms., and subsequent doses of 1.0 gm. every eight hours continued in this manner until six full days of normal temperature ensued. The febrile response to therapy is represented in Figure 6. For 24 hours after starting

Chloromycetin all symptoms were greatly magnified and the patient felt worse. Decided clinical improvement marked by reduction of muscle aches and increase in strength and vigor was apparent on the second treatment day. The temperature was normal after two full days of treatment. Convalescence thereafter was rapid. A total of 29.0 gms. of Chloromycetin was administered over a period of 10 days. The highest titer attained for *B. abortus* was 1/1280. Exactly 30 days after discharge from the hospital or 31 days after the last dose of antibiotic a low grade evening fever of about 99.4° F. was noted. These rises in temperature gradually increased to 104° F. when diaphoresis, muscle pains and gastrointestinal disturbances were experienced. Chloromycetin treatment, utilizing the prior schedule, was reinstituted, and the temperature returned to normal two days later. Blood taken during this febrile relapse did not reveal *Brucellae*. Judging from the rapid response after treatment with Chloromycetin, the causative organism had not gained resistance to the antibiotic.

DISCUSSION

In employing the chorioallantoic membrane of the chick, Goodpasture (10) demonstrated that *Brucellae*, similar to the rickettsiae, are obligate intercellular parasites which multiply within the cytoplasm of ectodermal cells. The highly specific effect demonstrated by Chloromycetin in rickett-

FIG. 6. (CASE NO. 7.) COURSE OF ILLNESS IN A PATIENT (MALE, AGE 24, 170 LBS.) WITH BRUCELLOSIS OF ABORTUS TYPE

Patient had a relapse 30 days after discontinuing Chloromycetin. Febrile response to retreatment immediate.

sial diseases (6, 11-13) is further evidence to suggest that this antibiotic might be expected to exert beneficial effect in brucellosis.

Spink and his collaborators (14) utilized the fertilized egg to demonstrate that a combination of streptomycin and sulfadiazine was sufficient to eradicate *Brucellae* from the tissues of infected embryos whereas they found that either drug used alone was incapable of achieving this effect. The clinical use of these combined agents in patients with brucellosis yielded more satisfactory results than had any prior treatment. In a series of treated cases these investigators (15) state that in the febrile patient normal temperatures were not sustained until the seventh to 10th days of treatment. Relapses with this form of treatment have been observed by others, and in our series of nine patients three had received treatment at an earlier date with the streptomycin and sulfadiazine regime, and were in active relapse with positive blood cultures when placed under therapy with the new antibiotic.

Detailed accounts of the successful treatment of brucellosis with aureomycin have been reported (16-18). In 24 patients with the more severe *B. melitensis* infection, Spink and his associates observed prompt reduction in toxemia and return of temperature to normal in 72 hours. Three relapses were encountered in this series up to the time of writing. In five patients with brucellosis, two proven to be abortus in type by blood cultures, we observed similar clinical improvement after aureomycin treatment (19). The temperature returned to normal in three days.

With Chloromycetin treatment in nine cases of active brucellosis we have observed abatement of symptoms within a short period and return of temperature to normal in three days after instituting treatment (Table I). One relapse occurred 30 days after discontinuing Chloromycetin. The response to retreatment was prompt. Only one patient with the more virulent *melitensis* type of brucellosis has been treated with this antibiotic. This patient responded favorably with return of temperature to normal in five days. It thus appears that both Chloromycetin and aureomycin exert similar favorable effect in amelioration of the symptoms of this disease, and it is not possible to affirm from the still limited accumulated evidence

which antibiotic is more effective. Long term observation of a large series of patients, varied treatment schedules and observations for possible toxic effects will need study before proper evaluation of these agents can be determined in a disease so variable in its clinical manifestations. Undoubtedly, until the optimum course of treatment is determined, additional relapses will occur at which time it will be highly instructive to observe the clinical effects after reinstituting Chloromycetin and to compare the drug sensitivity of the organism causing the relapse with the one isolated during the initial attack. It is probable that longer courses of antibiotic treatment may be necessary or perhaps periodic courses of antibiotic until a sufficient degree of immunity has developed.

CONCLUSIONS

Chloromycetin has been found to exert specific beneficial effect in nine patients with active brucella infection.

Further clinical testing will be necessary to determine the optimum therapeutic regimen.

ACKNOWLEDGMENTS

The authors wish to acknowledge the cooperation of Drs. J. E. Muse, Jr., T. Nelson Carey, A. H. Crowther, Baltimore, Maryland; R. S. McVaugh, Taneytown, Maryland; W. C. Stone, Westminster, Maryland; Paul Padgett, Veterans Hospital, Fort Howard, Maryland; A. A. Pearre, Frederick, Maryland; Capt. J. M. Lipnik, Fort Meade, Maryland; and Col. D. J. Waligora, Fort Jay, New York, in bringing these patients to our attention. Miss Ann Meredith rendered valuable technical assistance. Grateful acknowledgment is extended to Capt. H. L. Ley, Jr., of the Virus and Rickettsial Disease Department of the Army Medical Department Research and Graduate School, for assistance in performing Chloromycetin assays, and to the Maryland State Health Department Laboratory for collaboration in the bacteriological study.

THE EFFECT OF AUREOMYCIN AGAINST *BACTERIUM TULARENSE*¹

By JOHN C. RANSMEIER

(From the Department of Bacteriology and Immunology, Emory University School of Medicine,
Atlanta, Georgia)

The wide antibiotic spectrum of aureomycin prompted exploration for possible activity against *B. tularensis*. Its evidently low toxicity and its absorption in active form when administered orally would be decided advantages should it prove to be effective in tularemia.

EXPERIMENTAL STUDIES

The test organism. Studies were undertaken using a virulent strain of *B. tularensis* recently recovered from a patient who died of tularemic meningitis (1). The organism was agglutinated by known tularemic serum to full titer. It failed to grow on blood agar but grew well on solid medium containing 8% fresh rabbit blood, 1% dextrose, and 0.1% l-cystine in beef heart infusion agar base, prepared according to the method of Francis (2). Early cultures were preserved at -20° C. or 4° C. Fresh 24 to 48 hour transplants on blood dextrose cystine agar were used in all experiments, representing the second to seventh transfers from the original culture. The purity of each culture used was checked microscopically and on blood agar plates.

1. Inhibition of *B. tularensis* by aureomycin in culture medium

Method: Fresh medium was prepared by adding 8% rabbit blood to dextrose cystine beef heart infusion agar at 60° C. For comparison with control medium, aureomycin-HCl² from 20 mg. vials was dissolved in distilled water and introduced into flasks of this medium to yield final concentrations of 0.125, 0.25, 0.5, 1, 2, 4, 8, 16, 32, and 64 micrograms per ml. Exposure of the drug to 60° C. was momentary. The medium was quickly tubed, slanted, and hardened in the icebox. The elapsed time between dissolving the aureomycin and inoculation of the slants was five to six hours. The final pH of the medium was 6.8, and was not changed detectably by addition of aureomycin-HCl in concentration of 64 micrograms per ml.

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

² The aureomycin used in these studies was supplied through the courtesy of Lederle Laboratories Division, American Cyanamid Co.

The effectiveness of aureomycin in this medium against *B. tularensis* and *Staph. aureus* was tested. The staphylococcus used was inhibited by 1.5 but not by 0.75 micrograms of aureomycin per ml. in tryptose phosphate broth of pH 7.2 at 24 hours incubation. Turbid suspensions in broth were made from 26 hour blood dextrose cystine agar cultures of each organism. Slants containing 0 to 8 micrograms aureomycin per ml. were inoculated with 1 loopful of *Staph. aureus* or 3 loopfuls of *B. tularensis* and incubated at 37° C.

Results: Growth of *B. tularensis* did not become apparent on the control medium until 24 hours, at which time 0.5 microgram of aureomycin per ml. caused complete inhibition, while *Staph. aureus* required 1 microgram per ml. for inhibition (Table I). These early results are difficult to interpret because *B. tularensis* grows more slowly. After 36 hours the concentrations of aureomycin

<i>B. TULARENSE</i>	7	0.5	2.0	2.0	4.0	>8.0

* THIS STRAIN IS INHIBITED BY AUREOMYCIN 1.5 MICROGRAMS PER ML. IN TRYPTOSE PHOSPHATE BROTH AT 24 HOURS INCUBATION.

required to inhibit the two organisms were comparable, approximately doubling each 24 hours until 96 hours when growth of both was observed with 8 micrograms per ml. Earlier experiments showed that neither organism grew on slants containing 16 or more micrograms per ml. after incubation for one week.

Aureomycin in concentrations of 8 micrograms or less per ml. thus inhibited but did not kill *B. tularensis* and *Staph. aureus* inoculated on blood dextrose cystine agar slants. The progressive

daily increase in the concentration required for inhibition is best explained by deterioration of the drug on incubation at 37° C., as shown by Paine *et al.* (3) and Bliss and Chandler (4). The strain of *B. tularensis* tested was inhibited by concentrations comparable to those required for inhibition of a sensitive strain of *Staph. aureus*.

2. Effect of incubating *B. tularensis* with aureomycin in broth

Method: A turbid suspension of *B. tularensis* with a density of 4 on the McFarland scale (5) was prepared in tryptose phosphate broth from a 41 hour blood dextrose cystine agar culture. Aliquots of this suspension were added to equal volumes of broth, of aureomycin-HCl 100 micrograms per ml. in distilled water, and aureomycin 1000 micrograms per ml. in distilled water yielding final aureomycin concentrations of 0, 50, and 500 micrograms per ml. The initial pH of the broth was 7.2 and was not changed detectably by addition of aureomycin 50 micrograms per ml. It was reduced only to 7.05 by addition of 500 micrograms per ml. This is well within the pH range for maximal growth of *B. tularensis*. The suspensions were incubated at 37° C. for four hours, after which tenfold serial dilutions in broth were made.

Results: Inocula of 0.1 ml. of dilutions 10^{-1} to 10^{-10} were injected intraperitoneally into groups of four or five mice (Table II). All mice receiving dilutions 10^{-1} to 10^{-6} inclusive died. The control suspension incubated with broth had an LD₅₀ of 10^{-9} by the method of Reed and Muench (6). When incubated with 50 micrograms of aureomycin per ml. the LD₅₀ was $10^{-8.3}$ and with 500 micrograms per ml. it was $10^{-7.2}$.

Slants of blood dextrose cystine agar were also inoculated with three loopfuls of 10^{-1} and 10^{-3} dilu-

tions prepared from the three suspensions after incubation as described above. When incubated three days at 37° C. the slants from both dilutions of the control broth suspension and from the 10^{-1} dilution of the suspension containing aureomycin 50 micrograms per ml. showed a heavy confluent growth of *B. tularensis*. The 10^{-3} dilution of the suspension containing aureomycin 50 micrograms per ml. and the 10^{-1} dilution of the suspension containing 500 micrograms per ml. yielded innumerable separate colonies. The 10^{-3} dilution of the latter gave only 10–12 small colonies. Although after one week 65 colonies were visible, growth was still strikingly reduced as compared with cultures from the other suspensions.

It is evident that incubating a suspension of *B. tularensis* for four hours at 37° C. in the presence of aureomycin 500 micrograms per ml. killed an appreciable number of organisms. Questionable reduction of viable bacteria occurred in the presence of 50 micrograms per ml.

3. Subcutaneous aureomycin therapy of experimental tularemia in mice

Method: In therapeutic experiments standard suspensions of *B. tularensis* were freshly prepared by emulsifying growth from a 24 to 48 hour blood dextrose cystine agar culture in sterile saline and adjusting to a density of two on the McFarland scale (5). All suspensions were cultured on blood agar for purity and yielded no growth. Tenfold serial dilutions in broth were made. Young adult white male mice were inoculated intraperitoneally with 0.1 ml. of various serial dilutions. Control mice and those to be treated were inoculated with the same dilution. Simultaneously the LD₅₀ of the suspension was determined by titration in additional groups of mice. Aureomycin-HCl dissolved in sterile distilled water was administered subcutaneously to the mice designated for treatment. Mouse tularemia is apparently not contagious to cage mates except perhaps by cannibalism, which was prevented so far as possible by prompt removal of dead animals.

Procedure and Results: A pilot experiment was performed to determine the LD₅₀ for mice of a standard suspension of *B. tularensis*. Two of the higher serial dilutions were arbitrarily chosen for treatment (Table III). Inocula of 0.1 ml. of dilutions 10^{-4} to 10^{-9} inclusive were injected intraperitoneally into groups of four mice. Additional groups of four mice received the 10^{-7} and 10^{-8} dilutions. Treatment of the two latter groups with subcutaneous injections of aureomycin-HCl 0.5

mg. was begun immediately and continued three times daily at approximately eight hour intervals for five days, a total of 16 injections. (Each dose consisted of 0.25 ml. of a solution containing 2 mg. of aureomycin-HCl per ml. in distilled water.) All untreated mice inoculated with dilutions 10^{-4} to 10^{-8} inclusive and one receiving 10^{-9} died. The LD_{50} of the suspension was $10^{-8.7}$. All treated mice inoculated with the 10^{-7} and 10^{-8} dilutions survived 27 days after inoculation. It was evident that the inocula were small, about 10 and 1 MLD respectively, but 100% survival of the treated animals was noteworthy.

To investigate the possibility that *B. tularensis* was harbored in the tissues of the surviving treated animals, two mice were killed on the 27th day after inoculation with the 10^{-7} dilution. The spleen of one was enlarged to at least three times normal size, dark red, and showed definite pale focal areas on section. The spleen of the other was enlarged to perhaps twice normal size but showed only questionable foci. No other gross changes were noted. Spleen impression smears stained by Gram's method were negative for *B. tularensis*. The spleens were ground with sterile sand and emulsified in broth. Cultures yielded no growth on blood agar and blood dextrose cystine agar. Five mice were inoculated intraperitoneally with 0.1 ml. One died on the third day and one on the 12th, apparently neither of tularemia as shown by absence of typical autopsy findings and by negative spleen impression smears. The other three mice survived for 21 days. Accordingly, no evidence was obtained in this experiment to suggest that viable *B. tularensis* persisted in the

spleens of mice which survived as a result of aureomycin treatment.

To investigate the possible development of immunity in treated animals, the remaining six mice which had survived inoculation with the 10^{-7} and 10^{-8} dilutions were reinoculated intraperitoneally on the 27th day with 10^{-6} dilution of a suspension of *B. tularensis* used in a later experiment (see Table V). The inoculum represented 10+ MLD. All mice died on the third or fourth day after reinoculation. Autopsies on three showed typical changes of tularemia. Spleen impression smears were positive for *B. tularensis*, and the organism was recovered in pure culture from the spleens and heart bloods. There is thus no evidence that mice surviving inoculation with *B. tularensis* for 27 days as a result of aureomycin treatment had any appreciable immunity on reinoculation.

A second experiment was undertaken to determine the effect of smaller subcutaneous doses of aureomycin (Table IV). The LD_{50} of the suspension was $10^{-8.5}$. Groups of mice were inoculated with 10^{-6} dilution, and treatment was begun two hours later. All of 10 untreated mice died on the third or fourth day. Animals treated with 0.5, 0.25, 0.125, and 0.065 mg. of aureomycin subcutaneously three times daily at about eight hour intervals for a total of 16 doses (i.e., 1.5 to 0.19 mg./day, or approximately 75 to 9.4 mg./kg./day) remained well during five days therapy but all except three of 37 animals died after treatment was discontinued. That the deaths were due to tularemia was confirmed by positive autopsy findings and spleen impression smears. Mice receiving the largest dose of aureomycin (1.5 mg./day) survived longest. It did not seem feasible to

INOCULUM 0.1 ML. OF 10^{-6} DIL. OF MLD

use larger subcutaneous doses since edema, induration, and local necrosis were not infrequently noted following repeated injections of 0.5 mg. of aureomycin-HCl in 0.25 or 0.2 ml. of distilled water (2 to 2.5 mg./ml.). Local reactions were inconspicuous with concentrations of 1 mg./ml. or less.

The effect of duration and time of starting subcutaneous aureomycin treatment were next investigated (Table V). The LD_{50} of the suspension was $10^{-8.2}$. All of 20 control mice receiving the 10^{-6} dilution died on the third or fourth day. Groups of 10 mice which received the same inoculum were given 0.5 mg. of aureomycin subcutaneously at about eight hour intervals (1.5 mg./day or approximately 75 mg./kg./day) for 16 injections over a period of five days. One group received the first injection immediately before inoculation. A second group was started on therapy seven hours after inoculation. Two additional groups were given the same dosage of aureomycin started at the same times, but were continued on treatment for eight days or a total of 25 injections. All except one of the 40 treated mice remained well during therapy, but deaths began to occur on the fourth to sixth day after cessation of treatment and relatively few animals survived. Half of the group in which therapy was started just before inoculation and continued for eight days lived.

Two additional groups of 10 mice each, not shown in Table V, were included in this experiment and received the same inoculum at the same time. Treatment by subcutaneous injection was deferred until 28 hours after inoculation and continued for five and eight days respectively. These animals were likewise protected during therapy but deaths began to occur on the fifth day after cessation of treatment. All except one in

the group treated five days and two in the group treated eight days succumbed.

The best result (50% survival) was thus obtained when subcutaneous therapy was begun immediately before inoculation and continued for the longest period, *i.e.*, eight days. Whether more complete protection could be obtained with larger doses administered for a longer period, or with repeated short courses of treatment, is not known.

4. Oral aureomycin therapy of experimental tularemia in mice

Methods: Powdered drug from capsules was mixed with dry finely-ground Rockland mouse diet to yield concentrations of 0.5%, 0.25%, 0.125%, and 0.065%. Food was withheld for six hours and mice were then given the drug-containing diet *ad libitum*. By weighing the food taken it was found that 10 mice on the diet containing aureomycin 0.125%, inoculated intraperitoneally with *B. tularensis* on the second day, consumed an average of 3.68 gm. per mouse per day over an eight day period. If the average consumption be assumed to approximate 3.5 gm. per mouse per day, the amount of aureomycin taken in these diets may be estimated roughly as follows:

% of aureomycin in diet	Estimated amount of aureomycin consumed per mouse per day
%	mg.
0.5	17.5
0.25	8.8
0.125	4.4
0.065	2.2

In therapeutic experiments the drug-containing diet was begun, after a six hour fast, on the day prior to intraperitoneal inoculation with *B. tularensis*.

Procedure and Results: Groups of 10 mice were started on diets containing aureomycin 0.5%, 0.25%, 0.125%, and 0.065% while 20 control mice were given the basic diet without aureomycin. After 22 hours all mice were inoculated with a 10^{-6} dilution of a suspension of *B. tularensis* (Table VI). The LD_{50} of the suspension was $10^{-8.2}$. The treated animals were fed the aureomycin-containing diets for 14 days. All of the control mice died on the third or fourth day after inoculation. None of the animals receiving drug in the diet died during 14 days of therapy, but deaths began to occur on the third to fifth days after the basic ration was resumed. Nevertheless, significant numbers remained alive; a survival rate of 60% was observed in the mice fed diet containing 0.5% of aureomycin, with somewhat fewer survivals in the other groups. These results compared favorably with those observed after subcutaneous treatment.

INOCULUM 0.1 ML OF 10⁻⁶ I-P (10+MLD)
DIET STARTED 22 HOURS BEFORE INOCULATION

In studies on aureomycin therapy of relapsing fever, Heilman (7) found that the oral dosage required was in the order of five times the subcutaneous dose. If the same ratio pertains in tularemia, the diet containing 0.25% aureomycin might be estimated to be about equivalent to subcutaneous dosage of 1.5 mg. daily. In our experiments the results obtained with this diet fed for 14 days approximated those with subcutaneous injections of 1.5 mg. daily for eight days beginning immediately before inoculation (cf. Tables V and VI).

A second feeding experiment was undertaken to investigate the effectiveness of aureomycin in suppressing larger inocula (Table VII). Six groups of 10 mice were started on a diet containing 0.065% aureomycin. After 22 hours these were inoculated with the 10⁻² to 10⁻⁷ dilutions of a suspension of *B. tularense*. Control groups of six mice fed on basic ration without aureomycin were simultaneously inoculated with the 10⁻² to 10⁻¹⁰ dilutions. The treated animals received the

** DIET STARTED 22 HOURS BEFORE INOCULATION

drug-containing diet until eight days after inoculation, when it was replaced by basic ration. The LD₅₀ of the suspension was 10^{-8.6}. All of the control mice inoculated with the 10⁻² to 10⁻⁸ dilutions died on or before the fifth day. In the group of treated mice which received the 10⁻² dilution, representing about 1,000,000 MLD, five deaths occurred during the eight day treatment period, but only one of 50 mice in the other groups died during therapy. Partial suppression of tularemia was thus demonstrated by aureomycin against 1,000,000 MLD, and almost complete suppression was observed with inocula ranging from 10 to 100,000 MLD. However, after the drug-containing diet was withdrawn deaths began to occur and most of the animals succumbed by the 13th day after inoculation. The greatest percentage of survivals was noted in the group given the smallest inoculum, i.e., the 10⁻⁷ dilution, which contained about 10 MLD.

The size of inoculum appeared to be a decisive factor in determining ultimate survival of mice infected intraperitoneally with *B. tularense* and given aureomycin therapy, either orally or subcutaneously. With small inocula ranging from one to 10 MLD a very significant number of animals remained well. Although the drug exerted a striking suppressive effect against inocula up to 100,000 MLD, few mice which received inocula approaching or exceeding 100 MLD survived.

DISCUSSION

The first successful chemotherapy of experimental tularemia was reported by Heilman (8). He administered streptomycin subcutaneously to mice in divided doses totalling 1 mg. daily. Four injections of 0.15 mg. in saline and one of 0.4 mg. in beeswax and sesame oil were given in each 24 hours, and continued for 10 days beginning seven or eight hours after intraperitoneal injection of *B. tularense*. This regimen protected mice against inocula estimated at 10⁴ to 100⁴ MLD. When the total daily dose of streptomycin was reduced to 0.5 mg., only five of 12 mice were protected against 100⁴ MLD. The strain of *B. tularense* used was reported to be completely inhibited by 0.15 microgram of streptomycin per ml. *in vitro*. Because of differences in dosage form and schedule it is not possible to make a direct comparison between the results with aureomycin

reported herein and those obtained by Heilman using streptomycin.

Comparative studies on the activity of aureomycin, streptomycin, and chloromycetin in experimental tularemia have recently been reported by Woodward *et al.* (9). Using larger doses of aureomycin (3 mg./day intramuscularly for four days) they also occasionally obtained 100% survival of mice infected intraperitoneally with small inocula, but with larger inocula death regularly occurred after cessation of aureomycin treatment. They concluded, however, that aureomycin was more effective than streptomycin or chloromycetin in delaying death of mice infected with *B. tularensis*.

Because experimental tularemia in the mouse is an overwhelming septicemic disease with 100% mortality, it is a severe test of a chemotherapeutic agent. It is difficult to apply the results obtained to the human disease, either in general terms or in the more delicate matter of dosage required. When significant activity against *B. tularensis* has been established, both *in vitro* and in mice, carefully controlled clinical trial is the only means of evaluating the usefulness of a new antibiotic in human tularemia.

Woodward *et al.* (9) reported three tularemia patients in whom aureomycin was considered to be effective, and we have also treated three cases with apparently good results (1). Further cautious clinical trial of aureomycin in human tularemia is strongly indicated.

SUMMARY

Aureomycin exerted definite activity against a virulent strain of *B. tularensis*, *in vitro* and *in vivo*. When the drug was incorporated into blood dextrose cystine agar, *B. tularensis* was inhibited by 0.5 microgram per ml. at 24 hours and 2 micrograms per ml. at 48 hours. Its sensitivity was comparable to that of a strain of *Staph. aureus*. In concentrations of 8 micrograms or less per ml., aureomycin was bacteriostatic. However, when a suspension of *B. tularensis* was incubated for four hours in the presence of 500 micrograms per ml., appreciable numbers of organisms were killed as demonstrated by culture and titration in mice.

Furthermore, aureomycin administered subcutaneously or orally demonstrated a striking sup-

pressive effect in mice inoculated intraperitoneally with *B. tularensis*. Almost all animals survived treatment periods ranging from five to 14 days, but most of them died after cessation of therapy. With inocula between 10 and 100 MLD, about 50% survival resulted from subcutaneous therapy with 1.5 mg./day (75 mg./kg./day) given in three divided doses starting immediately before inoculation and continued at about eight hour intervals for eight days. Treatment achieved 100% protection in small groups of mice inoculated with 1 to 10 MLD.

Administration of 0.065% aureomycin in the diet of mice infected intraperitoneally with *B. tularensis* produced partial suppression of 1,000,000 MLD and almost complete suppression of 10 to 100,000 MLD during eight days therapy but most of the animals died after treatment was discontinued. Four of ten treated animals receiving only 10 MLD survived.

A careful trial of aureomycin in therapy of human tularemia is indicated.

THE CONCENTRATION OF AUREOMYCIN IN URINE AND CEREBROSPINAL, PLEURAL AND ASCITIC FLUIDS AFTER ORAL AND INTRAVENOUS ADMINISTRATION¹

By HARRY F. DOWLING, MARK H. LEPPER, ESTON R. CALDWELL, JR.,
RICHARD L. WHELTON, AND ROBERT L. BRICKHOUSE

(From the George Washington University Medical Division, Gollinger Municipal Hospital,
and the Department of Medicine, George Washington University, Washington, D. C.)

During our previously reported studies (1) on the absorption of aureomycin in humans after oral and intramuscular administration, we found that aureomycin was sometimes present in the cerebrospinal fluid. We have extended these studies in order to determine the conditions under which aureomycin will be detectable. The present paper includes the cerebrospinal fluid findings in 26 subjects with no inflammation of the central nervous system and in one patient with meningitis and two with encephalitis together with a small number of tests for aureomycin concentration in urine and in pleural and ascitic fluids.

METHOD

Cerebrospinal fluid specimens were obtained simultaneously with specimens of serum on two patients after a single dose of 2 gm. by mouth, on four after a single 1 gm. dose, and on 18 patients who were under treatment with aureomycin² in doses of 250 to 500 mg. every three hours by mouth. Five subjects were given a single intravenous dose of 500 mg. of aureomycin and a single specimen of blood and spinal fluid was taken three or four hours later. One patient with a pleural effusion was given oral aureomycin and simultaneous blood and pleural fluid specimens were obtained. The same procedure was followed in the case of a patient with cirrhosis and ascites.

Aureomycin concentrations were determined by a modification of Dornbush's (2) method, as previously described by us (1).

RESULTS

Distribution into the Cerebrospinal Fluid. As shown in Figure 1, aureomycin was present in the cerebrospinal fluid in only one among 17 specimens obtained within the first 12 hours of aureomycin therapy. Five patients were given a single

intravenous dose of 500 mg. of aureomycin in 25 cc. of arginine or leucine buffer solution. Three to four hours later the serum aureomycin concentration was 2 μ g. in each instance. At the same time 0.06 μ g. was present in the cerebrospinal fluid of one patient and 0.03 μ g. in the fluid of two patients, while detectable amounts of aureomycin were not demonstrated in the cerebrospinal fluids of the two remaining patients.

All of the 16 specimens of cerebrospinal fluid obtained from patients who had received the antibiotic for 23 hours or more contained demonstrable concentrations of aureomycin. The presence of meningitis apparently made no difference in the cerebrospinal fluid concentration attained. Two specimens obtained from patients with encephalitis contained unusually high cerebrospinal fluid concentrations compared with serum concentrations. In general, the higher the serum concentration the higher the concentration in the cerebrospinal fluid. There was no indication that after the first 24 hours there was any further rise in the spinal fluid concentration unless the dose of aureomycin was increased sufficiently to cause a rise in the serum concentration.

Distribution in Pleural and Ascitic Fluids. One patient with a pleural effusion had a concentration of aureomycin in the serum of 0.5 μ g./cc. and 0.125 μ g./cc. in the pleural fluid (Table I). Another patient with cirrhosis and ascites had concentrations of aureomycin in the ascitic fluid of 0.125 and 1.0 μ g. at the same time that serum concentrations were 0.5 and 1 μ g., respectively. A third concentration of 0.03 μ g. was obtained at a time when a simultaneous serum level was not done.

Excretion in the Urine. The amount of aureomycin excreted in the urine after oral and intravenous administration is shown in Table II. One patient was given a single dose of 1 gm. and another 700 mg. by mouth. The concentration of the antibiotic in the urine was 64 to 128 μ g./cc. in

* Had prostatic hypertrophy and urinary retention.

DISCUSSION

It is apparent that after the first 24 hours of therapy with the doses of aureomycin in common use, detectable levels of the antibiotic are consistently present in the cerebrospinal fluid. Larger doses, producing higher serum concentrations, should result in higher cerebrospinal fluid levels. In some instances the antibiotic is present three hours after an intravenous injection of 500 mg. It is likely that higher intravenous doses might assure the presence of the antibiotic in the spinal fluid in all cases within a few hours. It is of interest that the one patient with pneumococcal meningitis whom we treated with oral doses of aureomycin recovered. The concentration of aureomycin in his cerebrospinal fluid was not detectable 12 hours after the start of therapy, but was 0.05 to 0.13 $\mu\text{g.}$ thereafter. This patient received two doses of sulfonamides before aureomy-

cin was started. These may have prevented the progression of the meningitis before aureomycin was available at the site of the infection, although we doubt that they could have been responsible for the patient's recovery. In this connection, it is of interest that we have found the sensitivity of 26 strains of pneumococci to range between 0.01 and 0.16 $\mu\text{g.}$ of aureomycin. Seventeen of the strains were sensitive to 0.02 $\mu\text{g.}$ or less. Our preliminary studies show that aureomycin can be transmitted into the pleural and ascitic fluids when it is administered systemically. Whether this is true in all cases and whether the concentrations are sufficient for therapeutic effects are problems which await further study. The large volumes of urine obtained in some cases, and our observations on a number of patients under treatment with aureomycin, lead us to believe that aureomycin has a diuretic effect. The amount excreted is directly related to the serum concentration, the pH of

serum concentration to urine concentration being in the neighborhood of 1:100. This makes it likely that aureomycin is excreted as a glomerular filtrate. From our previous studies (1), which indicate that the serum concentrations are very low after 12 hours, and the fact that there is a constant serum-urine ratio, it can be deduced that the major portion of the aureomycin recoverable in the urine is excreted within 12 hours and that only relatively small amounts are recoverable thereafter. It would appear, therefore, that at most, only 15 to 20 per cent of the antibiotic will be recovered in the urine even after intravenous administration. Collins and his associates (3), measuring complete aureomycin excretion in two patients, found that 11 to 13 per cent was recovered after oral administration. The data available at present indicate, therefore, that the major portion of an intravenous dose of aureomycin is disposed of by methods other than urinary excretion and that the percentage recoverable in the urine is so small that the figure is of relatively little value in estimating the completeness of absorption from the gastro-intestinal tract.

SUMMARY

1. Among 17 specimens of cerebrospinal fluid obtained during the first 12 hours of oral administration, aureomycin was detectable in only one. When five patients were given an intravenous dose of 500 mg., detectable concentrations were present

in the cerebrospinal fluids of three patients within four hours. Aureomycin was present in all 16 specimens obtained 23 or more hours after the first oral dose, the concentrations ranging from 0.03 to 1 μ g. and being approximately related to the serum concentration present at the same time.

2. Aureomycin has been found in the pleural and ascitic fluids of two patients after oral administration.

3. Urine studies on eight patients showed an aureomycin concentration of 12.5 to 100 μ g./cc. during the first hour after oral or intravenous administration, depending upon the height of the serum concentration and the volume of urine excreted. The ratio of the aureomycin concentrations of serum to urine was approximately 1:100.

ACKNOWLEDGMENT

We wish to thank Mrs. Joan R. Broyhill, Miss Pearl Roberts and Miss Myrtle I. Meyer for technical assistance.

CLINICAL EXPERIENCE WITH AUREOMYCIN^{1,2}

BY JOHN C. HARVEY, GEORGE S. MIRICK, AND ISABELLE G. SCHAUB

(From the Johns Hopkins University School of Medicine, Department of Medicine, Baltimore)

During the past nine months a study has been made by members of the medical service at the Johns Hopkins Hospital concerning some of the possible therapeutic uses of aureomycin. Forty-eight patients with a variety of infectious processes were selected for treatment. In many cases the patients had been treated unsuccessfully with one or more chemotherapeutic agents before aureomycin was given but in each instance an effort was made to curtail other drugs during the period that aureomycin was used. Whenever possible the infectious agent was recovered before treatment with aureomycin was started, and other cultures were made during and following this therapy. The sensitivity to aureomycin of the bacteria recovered was tested *in vitro* in each instance.

Certain studies were made to evaluate the possible toxicity of the drug. The patients were examined daily for evidence of rashes or untoward symptoms. The blood and urine were examined before, during, and after treatment. The liver function of 37 cases was tested before and after treatment, by the thymol turbidity, cephalin flocculation, and BSP excretion tests and serial electrocardiograms were obtained from 39 cases. No patient developed drug fever or dermatitis, and no signs of toxicity to the bone marrow, kidneys, liver, or myocardium were noted. Twenty-six of the 48 patients complained of nausea or epigastric distress. Diarrhea was noted in addition in nine cases. The gastrointestinal symptoms seemed to depend on idiosyncrasy and some patients could take large doses without discomfort. In general, the same dose caused less discomfort when divided into small amounts given frequently rather than large amounts at wider intervals. Aureomycin was better tolerated when given with food or with

a buffer like Alugel but its effectiveness might be decreased by this procedure since it is known to deteriorate in alkaline environments. Many patients developed tolerance to aureomycin as treatment progressed. In only five cases was therapy stopped because of uncontrollable vomiting. It is of interest that four of these five were ambulant patients with sinusitis.

The patients have been divided into separate groups according to the diagnosis. The therapeutic results in each group will be considered separately.

Fifteen cases of urinary tract infection were treated. Six had chronic pyelonephritis, four had acute cystitis, three had post-operative infection with associated bacteremia, one had hydronephrosis, and one had a horse-shoe kidney. In 11 cases the infecting bacterium was *E. coli*, in two cases enterococcus, and in one, *Pseudomonas aeruginosa*. Each of the infecting strains of *E. coli* was inhibited *in vitro* by aureomycin in concentrations between 0.7 and 15 $\mu\text{g./cc.}$ of medium. The strain of pseudomonas was resistant to 50 $\mu\text{g./cc.}$ Fourteen of the 15 cases had not responded to other types of chemotherapy. The patients each received a total dosage of 4 to 32 gm. with an average of 13.2 gm. The results obtained were uniformly satisfactory except in the case of infection due to pseudomonas. All symptoms subsided within one to four days (average three and two-tenths days). In every instance the urine was sterilized. The follow-up periods are not yet very long but so far only the one patient with pseudomonas infection has had recurrence of the disease. Two other patients, following cystitis due to *E. coli*, developed stubborn infections due to proteus. This led us to avoid catheterization of other patients.

these patients recovered. The temperature reached normal on the second to fifth day of treatment (average four days). This corresponded with the 11th day of disease, or five and one-half days after hospitalization commenced. Nine additional patients with primary atypical pneumonia, admitted to the hospital during the study period, received no chemotherapy. The results are summarized in Table II. The first five listed were alternate admissions to the six treated cases. In this untreated series the results observed were just as satisfactory as in the treated cases. The temperature reached normal on the average after 10.1 days of disease and four and seven-tenths days of hospitalization. The results observed in these small groups of patients fail to indicate that aureomycin in the dosage employed affected the course of this disease. It seems obvious that larger groups of patients with adequate controls are necessary to settle this point.

Three patients with lung abscess were treated. Two had chronic infections for six and nine months, respectively. The third was acutely infected. The abscess in one patient was secondary to a pulmonary adenocarcinoma. From this case a pure culture of *E. coli* sensitive to 0.75 µg./cc. of aureomycin was obtained from the pus. No improvement had been noted following treatment with penicillin and sulfadiazine. After treatment with aureomycin, 4 gm. daily for 20 days, subjective improvement was noticeable and the temperature returned to normal. Subsequently, however, both fever and symptoms recurred and surgical drainage was necessary. It is of interest that the pus then contained no *E. coli* but instead a pure culture of proteus.

The second chronic case with a mixed infection resistant to penicillin and streptomycin was markedly improved after receiving aureomycin 4 gm. daily for six weeks. Fever and sputum disappeared and roentgenographic examination revealed a normal lung. The third patient had multiple acute abscesses due to staphylococcus and improved dramatically when treated with aureomycin although penicillin had seemed ineffective. Six patients with sinusitis were treated with satisfactory results.

An additional group of nine patients with different types of infections was treated with good results. These included two cases of lymphopathia venereum, and one case each of Rocky Mountain Spotted Fever, rat bite fever, tonsillitis due to *Streptococcus pyogenes*, meningitis due to *E. coli*, meningitis due to pneumococcus Type XIX, rodent ulcer, lobar pneumonia, and chronic brucellosis. One case of chronic ulcerative colitis showed marked symptomatic improvement on treatment.

Unsatisfactory results were observed in five additional patients comprising one case each of thyroiditis, pemphigus, sarcoid, osteomyelitis, and typhoid fever.

Four patients with bacterial endocarditis were treated. In two the infections, due to *Streptococcus fecalis*, developed following the Blalock-Taussig operation. The other two patients developed spontaneous infections due to microaerophilic streptococci. The courses of these four patients are summarized in Figures 1-4. In the case of K. S. (Figure 1) the *Streptococcus fecalis* was

FIG. 5. COLONIAL FORMS OF *Streptococcus fecalis* GROWN ON AGAR PLATE CONTAINING BLOOD

A represents the large colonies formed by the strain recovered before treatment, inhibited by 0.75 $\mu\text{g./cc.}$ of aureomycin, but not less. B represents smaller colonies formed by the strain recovered after treatment with aureomycin, inhibited by 6.2 $\mu\text{g./cc.}$ of aureomycin, but not less.

TABLE III
Characteristics of *Streptococcus fecalis*—Strain AG

Characteristics	Strain No. 1 before therapy	Strain No. 2 after therapy
Sensitivity Aureomycin	0.75 $\mu\text{g./cc.}$	6.2 $\mu\text{g. cc.}$
Sensitivity Penicillin	7.8 u. cc.	7.8 u./cc.
Colonies Blood agar	large, translucent	small, more opaque
Growth— F.S. broth	6 hr.—500,000,000/cc. 24 hr.—1,500,000,000 cc.	6 hr.—50,000,000 cc. 24 hr.—50,000,000/cc.
Morphology	Large, elongated G+ cocci in pairs, groups, and short chains	Same
Growth in broth	Smooth	Smooth
Heat resistance 62° C.—30 min.	—	+
Eugonic milk	Reduced, coagulated, peptonized	Same
Liquefaction of serum	Liquefied	Liquefied
Liquefaction of gelatin	—	—
Optimal growth pH	6.3	7.0
Substrate utilization	Hydrolyzed	Hydrolyzed

the temperature became normal, clinical improvement was progressive, and the patient remains well five months since discharge from the hospital. In the other three cases, evidence of infection persisted during or subsequent to the aureomycin treatment.

It is of interest to note that the strains of streptococci recovered from the blood stream of cases B. C. and A. G. after aureomycin treatment showed greater resistance to the bacteriostatic effect of aureomycin *in vitro* than the original strain obtained before treatment. The increases noted were 16 fold and eight fold, respectively. Detailed studies were made of the strain obtained from A. G. It was noted that the resistant strain grew more slowly in broth and the colonies on agar plates containing blood were smaller than those of the original sensitive strain. All the other characteristics tested were identical. These observations are shown in Table III and Figure 5. The changes in growth rate and colonial form are

suggestive of those described by Eriksen (1) for staphylococci resistant to penicillin. The small resistant variants of this streptococcus were unstable and reverted quickly to the fast growing aureomycin sensitive type.

It is quite obvious that in each case the drug has some therapeutic effect in that the temperature became normal and blood cultures became sterile. The reasons for the subsequent reappearance of the bacteremia in two of the cases infected with organisms quite sensitive *in vitro* are not now obvious. The development of increased resistance as illustrated in the two cases B. C. and A. G. may have played a part in the ultimate failure in therapy but there may be other equally important

factors such as the inability of aureomycin to penetrate the vegetations.

In summary, aureomycin is a non-toxic drug which may be useful in a variety of infectious diseases. In our experience the results in urinary tract infections were particularly good. The relatively slow deterioration of aureomycin in acid environments may contribute to its effectiveness in this type of infection. The use of aureomycin in combination with other antimicrobial agents was not tested.

THE CLINICAL EVALUATION OF AUREOMYCIN^{1, 2, 3}

By HENRY BRAINERD, EDWIN H. LENNETTE, GORDON MEIKLEJOHN,
HENRY B. BRUYN, JR., AND WILLIAM H. CLARK

(From the Infectious Disease Laboratory⁴ of the San Francisco Hospital and the State of California Virus and Rickettsial Disease Laboratory, Berkeley, California)

Aureomycin (1), an antibiotic agent derived from *Streptomyces aureofaciens*, has been demonstrated to have therapeutic activity against a wide variety of bacterial, rickettsial, and viral pathogens. *In vitro* and *in vivo* activity has been observed against most gram-positive cocci, and gram-negative cocci and rods (1-6). In addition, *in vivo* activity, has been shown against the rickettsiae of the typhus, Rocky Mountain spotted fever, scrub typhus, and Q fever groups, as well as against the viruses of lymphopathia venereum and psittacosis (7, 8). Animal toxicity has been noted to be very slight (9).

Successful clinical trials have been reported in a wide variety of bacterial and rickettsial infections, as well as infections due to lymphopathia venereum virus and the causative agent of primary atypical pneumonia (4, 6, 10-24). Toxic reactions have been few and insignificant. Since the number of patients reported with each type of infection has been small, and since all patients were treated by the oral or intramuscular routes, we are documenting the results of clinical trial of aureomycin in 116 patients observed since May, 1948. Many of these patients received aureomycin by the intravenous route. Assays of serum concentrations of aureomycin were carried out in most patients by means of a method previously described (25). *In vitro* sensitivity tests on the infecting organisms were carried out wherever pos-

sible. Studies on the clinical pharmacology of aureomycin are being presented elsewhere (26).

MATERIALS AND METHODS

The majority of the patients represented in the present report were treated with aureomycin while hospitalized at the San Francisco Hospital or the University of California Hospital. In several instances, the patients were treated in other locations under the guidance of one or more of the present investigators, and laboratory studies were carried out under their direction. Most of the viral and rickettsial isolations and serological procedures were carried out at the State of California Virus and Rickettsial Disease Laboratory. The assays of serum aureomycin concentration were carried out at the Infectious Disease Laboratory, as were determinations of the aureomycin sensitivity of the infecting bacterial organisms (Tables Ia and Ib).

All patients were accepted for inclusion in the investigative series only when adequate clinical and laboratory criteria for diagnosis were satisfied.

Dosage and Route of Administration

Adult patients in this series taking aureomycin by mouth generally received 1 gram every four to eight hours. Most patients received 1 gram every six hours. In many infections this dosage schedule may prove to be excessive. Several patients suffering from primary atypical pneumonia have responded satisfactorily to 0.5 gram every six hours, and 0.5 gram every eight hours seemed adequate in one patient whose urinary tract infection was due to a moderately susceptible organism. On the other hand, large doses may be required to produce satisfactory results in patients infected with resistant bacteria such as *Pseudomonas aeruginosa* and *Proteus vulgaris*, in typhoid fever, and in Q fever.

Sixty-eight⁵ individuals received 337 intravenous injections of aureomycin. In 327 instances the aureomycin was dissolved immediately before injection in a solution containing 131 mg. of *l*-leucine per 5 cc. A concentration of 10 mg. of aureomycin per cc. was used. A 0.784 per cent sodium carbonate solution appeared to be a satisfactory diluent in 10 intravenous injections. As many as 36 injections of 100 mg. were given in an individual patient without untoward result. The individual intravenous dose varied from 40 to 200 mg. Intravenous doses of 50 to 100 mg. have been demonstrated to produce serum levels of from 2.5 to 10 μ g. five minutes after

⁵ This figure includes 12 normal individuals who received intravenous aureomycin in the course of pharmacological experiments.

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

² Aided by grants from C. S. Howard Donation and the Fleishner Endowment Fund.

³ The aureomycin used in this investigation was provided by Lederle Laboratories, Division of the American Cyanamid Company.

⁴ This laboratory is supported by the Divisions of Medicine and Pediatrics of the University of California Medical School and by the Department of Public Health of the City and County of San Francisco, California.

injection (25, 26). Concentrations of aureomycin in excess of 0.15 $\mu\text{g. per cc.}$ usually persisted from six to eight hours. Combined simultaneous oral and intravenous treatment resulted in serum concentrations as high as 20 to 80 $\mu\text{g. per cc.}$

Intravenous medication was used according to two general plans:

1) One or two intravenous doses were given initially, often combined with oral doses, to achieve an immediate high blood concentration of aureomycin. High serum levels of aureomycin often did not appear for one or more days when only oral administration was used. These initial priming doses were followed by maintenance on oral therapy (32 patients).

2) Three intravenous doses, usually of 100 mg., were administered at six-hour intervals during the day supplemented by one oral dose at night during the entire course of treatment (22 patients). Two patients were treated satisfactorily with three intravenous injections daily without supplementary oral medication.

The therapeutic effects of intravenous medication did not appear to differ from those following from oral administration alone in infection due to susceptible agents. Treatment by the intramuscular route was abandoned following the very frequent occurrence of painful local reactions and the demonstration that measurable serum concentrations of aureomycin rarely resulted.

While the relationship of *in vitro* sensitivity tests of infecting organisms and optimum serum aureomycin concentrations to produce favorable clinical response is as yet unknown, such *in vitro* tests in this laboratory partially helped clarify in which types of infection success or failure would be likely to occur.

In this laboratory most strains of gram-positive cocci and *C. diphtheriae* were sensitive to less than 0.1 $\mu\text{g. per cc.}$, according to the method used. Most strains of *E. coli*, *A. aerogenes*, *E. typhosa*, *Salmonellae*, *N. meningitis*, *K. pneumoniae*, *H. influenzae*, and *Shigellae* were sensitive to less than 1.0 $\mu\text{g. per cc.}$ *Pr. vulgaris* and *Ps. aeruginosa* were found to be susceptible only to from 3.5 to 288 $\mu\text{g. per cc.}$ (26). Spontaneous development of aureomycin resistance following unsuccessful treatment was observed in only one instance, that of a urinary tract infection due to *E. coli*. In this patient the infecting organism was sensitive to 0.21 $\mu\text{g. per cc.}$ before the beginning of treatment, while an *E. coli* recovered during relapse was inhibited only by 285 $\mu\text{g. per cc.}$

Toxicity

No serious toxic effects of aureomycin were noted. Nausea and/or vomiting occurred in more than one-half of patients receiving oral doses of 1 gram every four or six hours. Occasionally this was sufficiently severe to prevent further treatment by this route. That this distressing symptom was principally local in cause was evidenced by the fact that only two of 68 patients receiving aureomycin intravenously experienced nausea and in neither instance was the symptom certainly attributable to medication. Patients receiving three intravenous and one oral dose per day did not experience significant

nausea. On several occasions positive guaiac reactions for occult blood were observed in the stools of patients receiving aureomycin by mouth. Nausea occasionally subsided spontaneously in spite of continuation of oral therapy. Aluminum hydroxide gels at times appeared to give relief, as did sedative and antispasmodic medications. Frequent or loose stools were commonly observed but did not prevent continuation of therapy. The serum concentration of aureomycin bore no relationship to untoward gastrointestinal manifestations.

Maculo-papular, urticarial, or scarlatiniform rashes were observed in six patients. In two of these the rash could have logically been ascribed to some other cause than aureomycin medication. Drug fever was considered a possibility in two instances. Vertigo occurred in two patients receiving aureomycin intravenously after only short periods of treatment and in the absence of unusually high blood concentrations. The significance of this observation is uncertain. "Black tongue" occurred in two patients. Two instances of glossitis in association with rashes were noted. Local spasm of veins during injection was observed very rarely. No sloughs resulted from extravasation outside the vein. Erythema and pruritus of the perineal area occurred in four patients. Intramuscular injection of aureomycin dissolved in Sorenson's phosphate buffer (pH 7.4) and combined with 2 per cent procaine almost invariably resulted in severe, painful, local reactions.

RESULTS

Typhoid, Salmonella and Shigella Infections

In this group of patients, the results following aureomycin therapy were variable, and for the most part could not be interpreted as showing a therapeutic effect of the drug. However, in certain cases the results were such as to convince one that the drug had been of specific clinical value.

In one of two carriers of *E. typhosa* who had no clinical disease, there was temporary absence of the organism during aureomycin therapy. The second carrier showed no change in the stool culture for *E. typhosa*. In a third patient who developed a biliary fistula following cholecystectomy and who showed the presence of *E. typhosa* in both feces and in the discharge from the fistula, there was healing of the fistula and abolition of the fecal carrier state following aureomycin therapy. Long-term follow-up of this case has not been completed at this time.

In nine cases of acute typhoid fever, only two showed a response to aureomycin therapy. The first of these patients, L. W., whose course is summarized in Figure 1 and given in detail below, was a 21-month-old child who was started on aureo-

FIG. 1

mycin on the 16th day of fever at which time the blood culture was positive for *E. typhosa*. She was given 1.0 gram of the drug daily and her temperature was within normal range in 48 hours. Her blood culture became sterile the day after therapy was started.

Case 1. L. W., white, female, age 21 months. This infant entered the University of California Hospital on June 22, 1948. On June 14 she had developed chills, fever and prostration which had continued unabated until hospital admission. A blood culture taken before entry proved to be positive for *E. typhosa*.

Physical examination revealed the rectal temperature to be 39.4° C. The child appeared severely ill and was irritable and uncooperative. No other positive physical findings were noted.

Urinalysis was negative. Complete blood count showed: Hemoglobin 11.0 grams per cent; red blood cells 4,100,000 per cubic mm.; white blood cells 16,000 per cubic mm.; neutrophils 74 per cent; lymphocytes 20 per cent; monocytes 6 per cent. Blood cultures taken on June 24 and June 27 were positive for *E. typhosa*. Stool cultures on July 2 and July 7 were negative. Urine culture on June 22 revealed only contaminating *E. coli*.

No clinical or bacteriological response followed administration of streptomycin and sulfadiazine from June 23

to June 27. On June 27 aureomycin therapy was begun. The patient received 0.16 gram by mouth every four hours until July 3. The temperature became normal in 48 hours and simultaneous general improvement was noted. Blood culture 24 hours after the institution of aureomycin was negative and the blood stream remained sterile thereafter. On July 2 and 3 an urticarial rash appeared over the trunk and faded spontaneously. The child had previously had urticaria after ingestion of several different foods. The possibility of aureomycin sensitivity remained uncertain. Further convalescence was uneventful.

The other patient showing a favorable response was also a child, age 22 months, who was started on 1.0 gram per day in four daily doses on the 13th day of disease at which time the blood culture was positive for *E. typhosa* and the temperature was 104° F. Her temperature dropped to below 100° F. within 48 hours and was within normal range within four days. There was marked symptomatic improvement within 48 hours.

Another patient was treated for a short time with aureomycin and then chloromycetin therapy was instituted. During aureomycin therapy the

blood culture became negative but the temperature course was unchanged. Two days after chloromycetin was started the temperature had dropped to within normal range and remained there. This case is summarized in Figure 2 and given in detail as follows:

Case 2. N. S., white female, age 43 (SFH 74120). Two weeks before admission to the San Francisco Hospital on March 9, 1949, this patient had noted the sudden onset of fever following the extraction of an abscessed tooth. She was admitted to another hospital where she had had slight diarrhea. Her blood culture was found to be positive for *E. typhosa* and her Widal test was

TABLE I-B

Summary of the results of aureomycin treatment in rickettsial, viral and miscellaneous infections

Disease	Total no. of cases	Results		
		Good	Equivocal	Poor

positive in a dilution of 1:320. She was then transferred to the San Francisco Hospital.

Past history was irrelevant. Examination at the time of admission revealed the temperature to be 40° C., pulse 100 per minute, respiration 24 per minute. The patient appeared toxic and lethargic, but was readily aroused. Numerous fresh rose spots were present on the abdomen. The spleen was not palpable. Physical examination was otherwise negative.

Urinalysis revealed one-plus albuminuria. Complete blood count showed: red blood cells 4,200,000 per cubic mm.; packed cell volume 34 per cent; white blood cells 3,800 per cubic mm.; neutrophils 66 per cent; eosinophils 2 per cent; lymphocytes 32 per cent. Blood culture was positive for *E. typhosa*. Urine and stool cultures were repeatedly negative for pathogens. Agglutinations with typhoid H and O antigens were both positive in a titer of 1:160. Chest X-ray was negative.

On March 11 the patient was started on aureomycin. She received 100 mg. intravenously every six hours. One oral dose of 1 gram was substituted for the night intravenous dose. Aureomycin was continued until March 14. Although the blood culture had become negative by March 12, no effect on the temperature or condition of the patient was apparent. On March 14 the patient was begun on chloromycetin. She received 1 gram every six hours by mouth until March 16 when the dose was changed to 0.5 gram every three hours by mouth. By March 17 the temperature had become normal and the patient appeared improved. She remained afebrile thereafter. Chloromycetin was discontinued on March 21.

In four of the remaining patients with acute typhoid fever, aureomycin therapy seemed to have caused a slight effect on the fever curve which could be interpreted as a temporary suppression of the infecting organism. In these patients the therapy caused no change in the course of the disease.

In four cases of infection due to organisms of the *Salmonella* group, unequivocally good results were obtained in only one, that of a septicemia without enteritis due to *Salmonella schottmulleri*. In this case, that of a 15-month-old male, penicillin, streptomycin, and sulfadiazine had had no effect on the blood culture which became negative 48 hours after starting aureomycin. The temperature came to within normal range after a similar interval. The possibility that this apparent response to the drug represents a spontaneous recovery is admitted but the rapidity of the temperature response led us to conclude that it was probably a therapeutic effect.

In three cases of enteritis due to *S. enteritidis*, *S. typhimurium* and *S. schottmulleri* a physical re-

FIG. 2

sults were noted. *S. enteritidis* and *S. schottmulleri* were not found in the stool cultures during treatment but promptly reappeared when therapy was stopped. In the case of *S. typhimurium*, the organism was not found in the stool after starting aureomycin and there was no recurrence.

Two cases of *Shigella* infections have been

treated, both with apparently good immediate results. A four-year-old girl with dysentery due to *Shigella* showed prompt bacteriological and clinical response with no recurrence following cessation of therapy. In the second case, a four-year-old boy with dysentery due to *Shigella flexner*, the stool cultures were free of this organism 24 hours after

TABLE II
The effect of aureomycin on infections of the urinary tract

Patient	Infecting organisms	Anatomical lesions	Result
L. A.	<i>A. aerogenes</i>	None	Rapid sterilization

starting aureomycin but the diarrhea continued for three more days. Long term bacteriological follow-up of this second case has not been completed.

While the total number of cases of infection due to organisms of the Typhoid-Salmonella-Shigella group is not large, it is probably a safe conclusion that, in our hands, aureomycin has been of doubtful value in most cases.

Infections of the Urinary Tract (Table II)

Aureomycin has been reported as favorably affecting infections of the urinary tract by others (14, 17, 24). Fourteen individuals with urinary tract infections, in all instances previously treated unsuccessfully with sulfonamides and other antimicrobial agents, were selected for therapy with aureomycin. In 11 of these patients chronic infection was certainly or probably associated with obstruction of the urinary passages. Three patients suffered from acute non-obstructive infections. All of the latter group responded quickly by sterilization of the urine and disappearance of symptoms. While temporary sterilization of the

urine was accomplished in 10 patients in the former group, excepting two who received very small amounts of aureomycin, relapse or reinfection occurred in all patients in whom follow-up cultures were obtainable. In only one instance was decrease in the sensitivity of the organism to aureomycin isolated during relapse observed. It was felt that aureomycin controlled the infection in the instances of hydronephrosis of pregnancy so that the fetus could be carried to term. In one instance pyelolithotomy was successfully accomplished during a period of suppression of infection by aureomycin. Infections due to *Pseudomonas aeruginosa* proved to be the most difficult to treat successfully.

Brucellosis

Three cases of brucellosis have been treated with aureomycin in the present investigation. Spink (18) has reported on 24 cases of brucellosis treated with aureomycin with favorable results.

The first case in the present report was that of a 21-year-old female who was treated for a period of 23 days starting on about the 63rd day of the

FIG. 3

disease. Her response was very satisfactory and the course is summarized in Figure 3 and a detailed case history follows.

Case 3. R. Y., white, female, age 21 (SFH 39899). The patient entered San Francisco Hospital on December 16, 1948, stating that she had had progressively severe bouts of nocturnal fever and sweating accompanied by joint pains for six weeks. In addition she had developed frequent nausea and vomiting and occasional epigastric pain during these episodes. Six weeks previous to the onset of her illness she had returned from several months' stay in Mexico. Her past history was irrelevant.

On examination the temperature was found to be 38.4° C., pulse 120 per minute, respiration 21 per minute. The patient appeared severely and chronically ill. There was slight generalized lymphadenopathy. The liver edge was palpated 3 cm. below the right costal margin. The spleen extended 7 cm. below the left costal margin. Physical examination was otherwise essentially negative.

Urinalysis revealed minimal albuminuria. Complete blood count showed: Hemoglobin 10 grams per cent; red blood cells 3,410,000 per cubic mm.; white blood cells 1,450 per cubic mm.; neutrophils 64 per cent; lymphocytes 38 per cent. Corrected sedimentation rate (Wintrobe) was 17 mm. per hour. Stool was negative for occult blood and pathogens. Chest X-ray, tuberculin and coccidioidin skin tests were negative. Agglutinations for typhoid and paratyphoid were repeatedly negative. Complement fixations for Q fever and psittacosis were negative. Brucella agglutinins were present in a titer of 1:320 on December 23, 1948 and gradually rose to 1:1,280 on January 10, 1949. After repeatedly sterile blood cultures, *Brucella melitensis* (type H2s) was isolated on January 3, 1949. On January 5 the patient received 50 mg. of aureomycin orally every six hours. On the following day this was increased to 250 mg. The patient received 1 gram every six hours from January 7 to January 28, and then 0.5 gram every six hours until January 30. Rapid defervescence occurred within 48 hours although the patient continued to run a low-grade fever until January 22. Symptomatic improvement coincided with the febrile response. On January 29 the patient had a chill followed by a transient febrile rise and was noted to have a macular rash over the entire body which faded rapidly by the next day. This patient has since remained entirely well.

The second case of brucellosis was that of a 32-year-old man whose treatment was started on the 15th day of disease and who received 4 grams per day for 13 days. The diagnosis in this case was based on a rise in Brucella agglutinin titer of from 1:500 on the sixth day of disease to 1:2,560 on the 13th day of the disease. His temperature, which had ranged around 100° to 103° F. for 15 days, fell to within normal limits within 48 hours and remained there.

The third individual, a 39-year-old woman who had had chronic brucellosis for four years, received 4 grams per day for 13 days after a preliminary three-day period during which she received 250, 500, and 750 mg., respectively. Amelioration of subjective symptoms was marked and almost immediate. Her expected bouts of low-grade fever did not occur during treatment or for two weeks afterward. At that time she again developed malaise and occasional low-grade fever. It was considered that aureomycin had probably exerted temporary suppressive effect on the infection.

Leptospirosis

Heilman (27) reported that aureomycin exhibited greater therapeutic effect on experimental infection with *Leptospira icterohemorrhagica* than did penicillin. A single severely ill patient was treated with aureomycin administered intravenously and orally from the sixth to 17th day of illness. Prompt amelioration of the symptoms appeared to result. The blood urea declined from 120 mg. per cent to 24 mg. per cent within one week. Liver function returned to normal more slowly. Although the rapid improvement could not certainly be attributed to aureomycin, it was felt that specific anti-spirochaetal effect was most likely. This case is presented in detail.

Case 4. J. J., white, male, age 42 (SFH 5389). This patient was brought to the San Francisco Hospital in an unconscious state on January 26, 1949. His wife stated that he had developed fever, chilly sensations, and malaise four days previously. He complained of severe aching in the shoulders, back and knees. He lost his appetite but did not vomit. His skin became yellow and his vision was blurred. On the morning of entry his speech became confused. Shortly thereafter he had three generalized convulsions and lapsed into coma. The patient was a sewer worker and had frequently encountered rats.

On examination his temperature was 37.8° C., pulse was unobtainable, respiration 22 per minute. He was completely unconscious. The skin and sclerae were icteric. Clotted blood was present in the right naris. The liver dullness extended three finger-breadths below the right costal margin. The spleen was not palpable. The reflexes were slightly more active on the right. During the 24 hours following hospital admission numerous subconjunctival hemorrhages appeared and purpuric spots were noted in the skin. The patient became semi-conscious but remained confused.

Urinalysis revealed mild albuminuria and a few hyaline and granular casts. Bile was absent. Hematological studies showed: packed cell volume—35 per cent; white

* Treatment started

blood cells 13,650 per cubic mm.; neutrophils 87 per cent; lymphocytes 13 per cent. A spinal puncture revealed a xanthochromic fluid containing 6,250 red blood cells per cubic mm. On January 28 *Leptospira* were demonstrated by darkfield examination of the blood. Agglutinins for *L. canicola* were present in a dilution of 1:100. No agglutinins for *L. icterohemorrhagica* were present. Darkfield examination of the blood on January 29 was again positive. Agglutinins for both *L. canicola* and *L. icterohemorrhagica* were present in a titer greater than 1:10,000 on February 4. Complement fixation reactions for Q fever and psittacosis were negative.

On January 28 the patient was begun on aureomycin therapy. He received 1 gram orally every six hours until February 8. In addition, 100 mg. were administered intravenously three times daily during the first five days.

The patient's sensorium cleared rapidly and his appetite and strength returned. The icteric index and blood urea were gradually decreased. The patient had little fever at any time after hospital admission. (See Table III.)

Q Fever

Twenty-nine patients, proven by serologic or animal tests to have Q fever, have been treated to the present time. A large number of these cases have been presented in a separate report (13). In 19 patients the drug was given orally. Two were treated by intramuscular injections and seven patients were treated by both the oral and intramuscular routes. One individual has been treated by the combined oral and intravenous routes.

The two patients treated by the intramuscular route alone recovered quickly but no conclusions can be drawn. They were treated early in this study and with what is now considered an inadequate dosage.

Fourteen of the 19 patients receiving aureomycin by the oral route alone were treated within seven days of onset of their illness. Treatment in the remaining four patients was begun on the 10th, 13th, 17th, and 23rd days, respectively, after onset of illness. Six patients became afebrile within 48 hours after institution of therapy and seven within

72 hours. Fever persisted in three patients for five days, however, in one for eight days, and in one for 13 days after beginning of treatment. The remaining individual had suffered an attack of Q fever two months previously and had continued to run a low-grade fever. Because of this persistent fever, he was treated with aureomycin orally for nine days and became afebrile on the first day of treatment. His fever did not recur and there was marked subjective improvement.

Therapy by the oral and intramuscular routes in six patients was begun on the third, fourth, seventh, tenth, 14th and 27th days respectively, after onset of illness. Temperature returned to normal in these six patients within 25, 26, four, 25, five and 18 days, respectively. Four of these patients were severely ill and large amounts of the antibiotic were given; because of severe nausea three of these individuals tolerated the drug poorly. The seventh patient in this group had run a prolonged convalescence with low-grade fever following an acute attack of Q fever nine weeks before; he became afebrile on the first day of treatment and remained afebrile.

One severely ill individual was treated by the combined oral and intravenous routes. He received a total of 2,100 mg. parenterally and 40.0 grams orally in two courses over a period of eight days. Treatment was begun on the 16th day of illness; 29 days later the patient remained febrile but improved, and the drug appeared to have had little effect on the course of the illness.

Primary Atypical Pneumonia

In the present investigation there were 16 patients treated with aureomycin whose clinical course and physical findings were such as to warrant a diagnosis of primary atypical pneumonia (28). These patients all had unequivocal serologic evidence of pneumonia; a total white blood count of below 15,000 and temperature re-

cordings of at least 102° F., before therapy was instituted. Several of these patients were exceptionally ill and none of those treated with penicillin had shown any improvement. Of the 11 patients from whom serum specimens were obtained at appropriate times there were seven who showed a cold agglutinin titer of 1:40 or more. Each of the two most severely ill patients had titers of 1:640, the remainder falling between 1:40 and 1:60.

In 14 of the 16 patients there was prompt initial symptomatic improvement and return of temperature to within normal range within 72 hours following institution of aureomycin. There were several whose response was extraordinarily rapid. The remaining two patients while showing clinical improvement remained febrile for somewhat longer periods. One patient appeared to relapse after drug had been stopped following good initial response. One of the patients who had shown a

good initial response appeared to relapse after the drug had been stopped, with return of low-grade fever and an increase in the X-ray evidence of pneumonia. This sequence of events has been observed to occur in other patients treated with aureomycin in another study (29). There follows a detailed case history of a patient with primary atypical pneumonia in whom treatment was carried out by the intravenous route alone. This case is summarized in Figure 4.

Case 5. T. B., white, male, age 17 (UCH 163710). This patient entered the University of California Hospital on February 25, 1949, complaining of a dry, hacking cough of two weeks' duration. On the day preceding hospital admission he had developed substernal pain and fever, and cough had become productive of a moderate amount of yellowish sputum. He had had asthma as a child but had suffered no attacks during the past 10 years.

On examination the temperature was 38.5° C., pulse 100 per minute, and respiration 20 per minute. The patient did not appear acutely ill but coughed frequently.

FIG. 4

FIG. 5

Squeaking fine and coarse rales were heard in both lung bases posteriorly. Physical examination was otherwise within normal limits.

Urinalysis was normal. Complete blood count showed: Hemoglobin 16.5 grams per cent; red blood cells 5,100,000 per cubic mm.; white blood cells 14,150 per cubic mm.; neutrophils 77 per cent; lymphocytes 12 per cent; monocytes 11 per cent. Corrected sedimentation rate (Wintrobe) was 17 mm. per hour. Throat culture was negative for pathogens. Chest X-ray revealed pneumonitis in both right and left lower lobes. Cold agglutinins were present in a dilution of 1:20 at the time of entry. This titer rose to 1:80 five days later.

100 mg. of aureomycin in leucine diluent was administered intravenously every eight hours from February 26 to March 1. The patient became afebrile and improved symptomatically within 24 hours. The rales disappeared from the chest by February 27. A chest film on March 2 revealed almost complete clearing of the previously noted pneumonitis.

Psittacosis

Trial of aureomycin in psittacosis was of particular interest because laboratory investigation suggested that this drug was highly effective *in vivo* (7). Penicillin has been found to be an ef-

fective therapeutic agent in a small number of reported cases as reviewed by Goggio (30). A larger number of cases with favorable therapeutic response is unreported (31).

Three patients with a diagnosis of psittacosis have been treated with aureomycin. In one the diagnosis was established by isolation of the virus and demonstration of an increase in complement-fixing antibody titer. The second diagnosis was based on the presence in the convalescent serum of complement-fixing antibody in a titer of 1:256. In the third, the diagnosis was based on a history of contact with infected birds, typical clinical course, and the fact that the patient's wife, who was ill at the same time, was shown to have a complement-fixing titer of 1:64. This patient himself did not develop complement-fixing antibody in significant titer. The diagnosis in the last two patients must be considered incompletely established. All three of these patients appeared to respond to aureomycin therapy.

The first case, E. F., is presented in detail below (Figure 5).

Case 6. E. F., white, female, age 64 (SFH 25740). The patient entered the San Francisco Hospital December 12, 1948, giving a history of anorexia of four weeks' duration followed by generalized aching and malaise for the three weeks preceding hospital entry. Two weeks before admission she developed a severe productive cough and high fever accompanied by sweats. On October 26, 1948, she had been given a parakeet which died one week later. No other members of the household had been ill, but two cases of psittacosis had recently been diagnosed as arising from parakeets obtained from the same source.

Past history was irrelevant except that the patient had had chronic productive cough for 40 years.

On examination the temperature was 39.5° C., pulse 86 per minute, and respiration 32 per minute. The patient appeared severely ill and drowsy. Dullness, diminished breath and voice sounds and fine and medium rales were noted over both lower lung lobes. Physical examination was otherwise essentially negative.

Urinalysis was normal. The blood count showed: Hemoglobin 11.2 grams per cent; red blood cells 3,210,000 per cubic mm.; white blood cells 5,150 per cubic mm.; polymorphonuclear leukocytes 60 per cent; eosinophiles 2 per cent; lymphocytes 38 per cent. Corrected sedimentation rate (Wintrobe) 42 mm. per hour. Mazzini test was negative. Blood culture was sterile. Throat culture revealed no pathogens. Stool culture was negative. Sputum was repeatedly negative for tubercle bacilli. Cold agglutinins were not demonstrated on December 16 and December 22. Complement fixation reaction for psittacosis was positive in a titer of 1:12 on December 14 and rose to 1:64 within a week. Psittacosis virus was recovered from the sputum by inoculation of cotton rats and mice. Agglutinations for typhoid, paratyphoid, and brucellosis were negative December 13 and 14. Complement-fixation for Q fever was negative. Chest X-ray revealed patchy accentuation of pulmonary markings radiating from both hila which was believed compatible with bronchopneumonia.

The patient received 300,000 units of penicillin procaine complex twice daily on December 13 and 14 at which time virus was still demonstrable in the sputum and fever unabated. On the evening of December 13 the patient was started on aureomycin 1 gram by mouth every six hours which she received until December 22.

50 mg. was administered intravenously at the time of the first oral dose. The patient became afebrile within 24 hours and remained so subsequently. Symptomatic improvement was prompt although the patient suffered from nausea and occasional vomiting considered due to aureomycin which was severe enough on one occasion to necessitate an intravenous dose of 100 mg. On December 17 the chest was negative to physical examination. Chest film taken on December 18 showed marked diminution of the inflammatory reaction previously seen. The patient was discharged as well on December 27, 1948.

The second patient, a male aged 38 years, was treated with aureomycin on the 12th day of the

disease and, following failure of response to repository penicillin, showed prompt symptomatic improvement. The temperature, which had been as high as 105° F. before therapy, dropped rapidly but a low-grade fever persisted for eight days.

The third patient, a male aged 47 years, who was admitted to the hospital on the fifth day of the disease, was treated with repository penicillin in doses of 300,000 units twice a day for five days. At the time penicillin was stopped the patient's temperature was 102° F. During the following three days, the patient's temperature fell gradually to normal but rose again to a level of 104° F. on the 15th day of the disease. Following institution of aureomycin therapy at this point, the temperature fell to below 100° F. within 48 hours and, with the exception of a single spike, remained below 100° F. thereafter with occasional temperature elevations to 99.4° F. until the 23rd day of illness. Within two days after starting the drug, marked symptomatic improvement was noted. These cases illustrate relatively poor response to repository penicillin and subsequent good response to aureomycin.

Miscellaneous Diseases

A small group of patients suffering from bacterial pneumonias and pneumonia of unknown etiology was treated with aureomycin. In addition, one patient with proven primary coccidioidal pneumonia received aureomycin in full dosage for five days without demonstrable effect. Of two patients with pneumococcal pneumonia, one became afebrile within 12 hours; the other continued to have low-grade fever after an initial critical response until the introduction of penicillin treatment. One child who had chronic cystic fibrosis of the pancreas on which staphylococcal pneumonitis was superimposed evidenced slight temporary depression of fever followed by relapse. In five patients with pneumonia of unproven etiology response to aureomycin varied from none to excellent. One patient died of septicemia and pneumonia due to *Pseudomonas aeruginosa* in spite of exceedingly high serum levels of aureomycin during one and one-half day's treatment.

Two patients with generalized peritonitis of appendiceal origin, but whose infecting organisms were unknown, responded satisfactorily to aureo-

mycin after becoming worse while under penicillin therapy. One patient with a peritoneal abscess, from which *E. coli* was cultivated, recovered promptly but the beneficial result was probably not attributable entirely to aureomycin, since colpotomy was done. One chronic fecal fistula following appendectomy did not close during two weeks treatment with aureomycin.

Dramatic healing was observed in an infant suffering from chronic pyoderma due to a penicillin-resistant staphylococcus. One of three patients with pemphigus appeared to go into remission while being treated with aureomycin, but new lesions developed 12 days after treatment was stopped. Another patient with pemphigus was treated during a period of apparent spontaneous improvement, making the result difficult to evaluate. A third patient did not improve. One patient who had herpes zoster ophthalmicus healed dramatically within one week of the beginning of aureomycin treatment. No apparent beneficial effect was observed in one patient who developed varicella while receiving aureomycin. Another patient with chickenpox developed no new lesions after aureomycin was begun on the second day of eruption. One patient who had erysipelas responded satisfactorily to aureomycin. The fever and bacteremia in two patients suffering from subacute bacterial endocarditis due to penicillin-resistant *Streptococcus fecalis* disappeared during treatment with aureomycin but recurred one and seven days respectively after the termination of long courses of therapy. In one of these patients the blood culture became sterile only after serum concentrations of aureomycin of 10 to 20 μ g. were attained.

Four patients with primary chancroidal ulcers of the penis and inguinal adenitis responded promptly to aureomycin therapy by rapid healing of the ulcers and subsidence of adenitis. One patient with inguinal adenitis due to lymphopathia venereum also appeared to respond satisfactorily.

No definite therapeutic effect was observed in three patients suffering from infectious mononucleosis. One patient with stomatitis, balanourethritis, conjunctivitis, and arthritis did not manifest therapeutic effect from aureomycin. No beneficial effect was observed from the treatment of Hodgkin's disease, acute leukemia, or carcinoma of the parotid gland.

DISCUSSION

Available data indicate that aureomycin will assume an important place in the physician's armamentarium. Its role as the preferred agent in the treatment of primary atypical pneumonia, psittacosis, leptospirosis, and infections of the urinary tract by *Streptococcus fecalis* seems likely to be established. The rarity of development of drug-resistant organisms would suggest its curative or suppressive value in the treatment of urinary tract infection due to susceptible organisms either in the presence or absence of obstructive lesions. Preliminary data would also indicate the promise of aureomycin in chancroid and lymphopathia venereum infections. Although acute brucellosis appears to be generally amenable to treatment with this antibiotic, its value in chronic brucellosis remains to be proven. In spite of excellent results in the majority of Q fever infections, treatment failures have been encountered. Results reported by others in typhus and Rocky Mountain spotted fever in small series of patients appear even more favorable (6, 10, 14, 16, 19, 22, 24). As yet inadequately explored is the place of aureomycin in the treatment of herpes zoster, varicella and herpes simplex.

As an alternative agent to penicillin in infections due to gram-positive cocci and Neisseriae, aureomycin offers great promise, especially where penicillin resistance is encountered. Furthermore, because of its very wide spectrum of activity, aureomycin may assume a dominant role in the treatment of acute infections where the exact etiology is unknown, as in "atypical" pneumonias of all sorts. The relative value of aureomycin and streptomycin in the treatment of infections due to gram-negative organisms susceptible to both agents cannot yet be estimated, but at least aureomycin will serve as an alternative agent in this field. Comparison of aureomycin and chloramphenicol in the treatment of rickettsial and certain viral and bacterial diseases must await carefully controlled studies.

In infections due to *E. typhosa* and the *Salmonellae*, aureomycin appears to be of limited usefulness. Although definite beneficial effect appears to result in some cases, frequent failures occur and cannot be entirely explained on the basis of inadequate serum concentrations. The activity of

aureomycin against infections due to *Ps. aeruginosa* and *Pr. vulgaris* appears to be very limited, even in the urinary tract where very high concentrations of the antibiotic are usually attainable (26).

Unlike penicillin and streptomycin, but somewhat reminiscent of the sulfonamide drugs, aureomycin often appears to exert a greater or lesser suppressive effect on the infecting agent without producing its complete destruction. Aureomycin may interfere with the development of complement-fixing antibodies in psittacosis and cold agglutinins in primary atypical pneumonia (29).

With the exception of nausea and vomiting, aureomycin compares favorably with penicillin in lack of significant toxic effects in relation to anti-infective activity. Even this side effect may be avoided by use of the intravenous route of administration. Furthermore, approximately one-tenth as much drug need be given intravenously as by mouth. Reduction of the oral dose or further purification of the antibiotic may also obviate gastrointestinal symptoms.

SUMMARY AND CONCLUSIONS

1. Aureomycin was used in the treatment of 116 patients with infections due to a variety of bacterial, rickettsial and viral agents.

2. The only significant toxic symptom encountered frequently was nausea and vomiting.

3. The intravenous route of administration, used in 68 individuals, proved to be an effective method of therapy, both when used to supplement oral medication to produce high serum concentrations of aureomycin, or to replace the oral route in the control of nausea and vomiting.

4. Aureomycin appeared to exert beneficial effect in acute brucellosis, leptospirosis, Q fever, primary atypical pneumonia, psittacosis, chancroid, lymphopathia venereum, generalized peritonitis, and many infections of the urinary tract.

5. Beneficial effects from aureomycin therapy appeared to be limited or absent in typhoid, *Salmonella*, *Shigella* infections, coccidioid pneumonia, infectious mononucleosis, varicella and subacute bacterial endocarditis due to *Streptococcus fecalis*.

FURTHER EXPERIENCES WITH INTRAVENOUS AUREOMYCIN THERAPY. A STUDY OF 116 CASES^{1,2}

BY MURRAY SANDERS, JOHN M. RUMBALL, CYRIL SOLOMON,
M. GONZALEZ SORET, AND NELDA I. RICCI

(From the University of Miami, Medical Research Unit at the V. A. Hospital, Coral Gables, Florida, and the French Hospital, New York, N. Y.)

The need for developing routes of administration for aureomycin other than oral has been apparent since the initial clinical trials with the antibiotic in the early months of 1948. To fill this need, studies on intravenous aureomycin were carried out simultaneously in the summer and fall of 1948 at St. Vincent's Hospital in New York by Rottino, Sanders, and Philip (1) and at the Harlem Hospital by Hill, Wright, Prigot, and Logan (2). The present report is an extension of the earlier work.

In the study at St. Vincent's, patients suffering from Hodgkin's disease received large doses of aureomycin intravenously up to 4 grams daily and toxicity data were thus obtained since the dosage was pressed until nausea and vomiting occurred. This knowledge has permitted us to proceed conservatively and without ill effects in using the intravenous route for therapy in numerous clinical entities. Detailed results on the clinical studies will be published elsewhere (3). At this time, it may be said that the intravenous method of administration has frequently produced dramatic therapeutic response and has proved to be an entirely practical procedure producing, at therapeutic levels, little or no side reactions.

It is to be noted that kidney and liver function tests made both at St. Vincent's and Harlem Hospitals at no time showed variation from the normal, even after massive doses of aureomycin intravenously were maintained for one week.

Indications for intravenous therapy

In general, the occasions are fairly obvious when the intravenous administration of aureomycin is

to be preferred to the oral or intramuscular routes. The desirability of rapidly obtaining a high aureomycin blood level with minimum discomfort is clear where:

- a. fulminating disease is present and the amount of antibiotic required would almost certainly cause gastro-intestinal disturbances;
- b. the patient does not have the benefit of gastro-intestinal absorption because he is vomiting (due to peritonitis, intestinal disturbances, etc.) or because he is in a comatose or semi-comatose condition; and
- c. the patient has attempted oral medication and has experienced marked discomfort without getting relief from the condition which was the original indication for therapy.

In addition to the extreme circumstances where intravenous aureomycin is urgently necessary, the most common use to which the intravenous method has been put by us is as an adjuvant form of therapy. From the previous blood level studies carried out at St. Vincent's, it was known that aureomycin injected into the blood reached a high level quickly and was also excreted with moderate rapidity (see Figure 1). This fact, as well as our reluctance to use intravenous medication unnecessarily, stimulated the study of combined intravenous and oral medication. It is in this realm that we believe that intravenous administration of aureomycin will find its greatest usefulness.

MATERIALS AND METHODS

Aureomycin hydrochloride³ is a yellow, highly soluble powder available in 50-mgm. vials. The procedures for preparing and administering the antibiotic followed in this study have been essentially the same as those recommended by Rottino, Sanders, and Philip. Unless special diluents are being investigated, the contents of each 50-mgm. vial are thoroughly dissolved in about 2 mls. of distilled water. If it is necessary or desirable to give

³ We wish to thank the officials of the Lederle Laboratories who so generously supplied large amounts of aureomycin and thus made the present study possible.

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

² Published with the permission of the Chief Medical Director, Veterans Administration, Department of Medicine and Surgery, who assumes no responsibility for the opinions expressed or conclusions drawn by the authors.

the patient parenteral fluids, the infusion indicated is started. The contents of the desired number of 50-mgm. vials of aureomycin in distilled water are then pooled and diluted in proper amounts of 1/6 M. lactate (Hartman's or Lactate-Ringer's) solution. After thorough mixing, the aureomycin in lactate is given as a rapid infusion. The aureomycin in distilled water is not mixed with the sodium lactate until the infusion is assembled because Harned and his associates (4) found that the antibiotic is stable in an acid medium and loses potency in an alkaline environment.

As far as the amount of lactate for the infusion is concerned, it is our impression that only an approximate quantity is necessary since the lactate merely serves as a vehicle for the antibiotic. It is important to remember that the buffering action of the lactate is helpful since aureomycin hydrochloride in distilled water has an approximate pH of 3.5 whereas the pH of the final mixture in lactate is approximately 5.5. The following quantities of 1/6 M. lactate solution as infusion vehicles for aureomycin varying from 50 to 1,000 mgms. are suggested. The schedule in Table I is on an entirely empirical basis and is one which has been satisfactory in our hands:⁴

TABLE I

A suggested ratio of aureomycin HCl to 1/6 M. sodium lactate for intravenous infusions

The bio-assay method

The bio-assay test for determining the amount of aureomycin in various body fluids was originated at the Lederle Laboratories by Dornbush and Pelcak (5). Since any attempt to study methods of administration depends largely upon an exact adherence to the bio-assay method, care was taken to make certain that the technique used in this study was in complete agreement with the test at Dornbush's laboratory.⁵

Comparative data: intravenous plus oral vs. oral medication alone

In presenting Figures 1-4 an attempt has been made to cull our experience with 116 patients on intravenous aureomycin therapy so that a basis

⁴ Additional work with intravenous aureomycin since the presentation of this paper has made it apparent that the amounts of 1/6 M. sodium lactate can be reduced to half those shown here.

⁵ We wish to thank Messrs. Dornbush and Pelcak for their cooperation and for providing purified antibiotic to be used as standard test material.

may be provided for therapeutic manipulation which may be useful in various clinical problems. During recent months, patients received various schedules of aureomycin therapy ranging from a single intravenous injection of 20 mgms. in an infant to a combined intravenous-oral course of an antibiotic in an adult, in whom the intravenous portion alone consisted of 76 500-mgm. infusions for a total of 38 grams (34 days of 500 mgms. b.i.d. and 42 days u.i.d.). In addition to the intravenous medication, 47 grams of adjuvant oral therapy were given. This patient, V. L., is alive and well and is apparently recovering from a chronic disease.

The primary purpose in demonstrating the results of the bio-assay in the following charts is to show the physician how he may proceed in a general fashion in obtaining aureomycin blood levels to satisfy special clinical requirements.

Figure 1 emphasizes the high concentration of aureomycin which can be obtained in the blood following a single injection of 1 gram intravenously. With two hours, a peak of 20 μ g. was reached but there was a fairly rapid drop to 10 μ g. two hours later. Although these high concentrations were not maintained for a long period of time under the given situation, a level of 5 μ g. was present up to 14 hours following the injection. This, of course, is a significant level which would be more than sufficient to combat most infections. Even after 24 hours, a significant level of 2 μ g. resulted. The technique of injection of 1 gram at a time appears to have little hazard judging the ease with which ten patients received such injections.

The advantage of using oral therapy in combination with intravenous therapy is illustrated in Figure 2. When compared with a single intravenous injection of 1 gram, the smaller intravenous injection of 350 mgms. given in conjunction with 250 mgms. by mouth every four hours produced significant blood levels which fluctuated between 3.2 and 6.4 μ g.

If this comfortable oral and intravenous schedule is continued for 24 hours (Figure 3), we see a dramatic rise to 12.8 μ g. with an excellent maintenance of aureomycin concentration for as long as 12 hours after cessation of therapy. Figure 3 also illustrates the difference between the oral regime

FIG. 1

men of 250 mgms. every four hours and the combined oral-intravenous schedule. On the oral therapy there is a slow rise with the level not exceeding 2 μ g. for the first ten hours. It is only

within 12 hours after the first capsule is taken that a concentration of 4 μ g. per ml. is reached in the blood. The peak of 5 μ g. is reached and maintained from 18 to 34 hours.

COMPARISON BETWEEN COMBINED INTRAVENOUS-ORAL AUREOMYCIN ADMINISTRATION AND A SINGLE INJECTION OF ONE GRAM OF AUREOMYCIN INTRAVENOUSLY

FIG. 2

COMPARATIVE BLOOD LEVELS
FOLLOWING ORAL AND INTRAVENOUS-ORAL ADMINISTRATION OF AUREOMYCIN

FIG. 3

By utilizing the information in Figures 2 and 3, it should be possible to maintain aureomycin concentrations at any desired level, subject, of course, to individual variations. The factor of individual

variation to similar dosage schedule has been observed with penicillin and streptomycin therapy. That the same factor must be considered in aureomycin therapy is apparent from Figure 4. The

FIG. 4

volunteer, M. S., was not a demonstrably ill individual and reached a peak concentration of 6.4 $\mu\text{g.}$ in his blood within 20 minutes after the intravenous injection of 350 mgms. This level fluctuated during the next 24 hours between 3.2 and 6.4 $\mu\text{g.}$ In contrast, patient H. M., suffering from infectious mononucleosis, and patient V. L., a post-hepatic cirrhotic, who were on the same intravenous and oral schedule as the volunteer, reached a peak of 3.2 $\mu\text{g.}$ and a maintenance level of between 1 and 2 $\mu\text{g.}$

Enhanced aureomycin blood levels by the use of caronamide

Since it has been shown that the blood concentration of penicillin can be enhanced by the oral administration of caronamide (6), an attempt was made to ascertain the effects of this drug (4-Carboxyphenylmethansulfonamide) on aureomycin absorption. To date, three⁶ patients have been studied and the result suggests that caronamide raises the blood level of aureomycin.

⁶ A temporary shortage of parenteral aureomycin has limited the number of patients under study with caronamide.

This phase of the work has been of particular interest to us since the assumption has been made by Beyer (7) that the action of caronamide in relation to penicillin absorption depends on the blockade by caronamide of specific enzyme systems responsible for penicillin transport through the renal tubules. Strauss, Richburg, Saba, and Alexander (6) have stated that caronamide has no effect on the plasma concentration of streptomycin when the antibiotic is given in multiple intramuscular injections. Inasmuch as aureomycin and streptomycin are derived from related microbial sources, it is curious that an enhancement action has been demonstrated.

One of the first patients to receive caronamide, 4 grams by mouth every four hours, was H. M. As is apparent from Figure 5, the increase of the aureomycin level following the use of caronamide was not dramatic, since a peak of 4 $\mu\text{g.}$ was reached in association with caronamide as against a peak of 3.2 $\mu\text{g.}$ when aureomycin was used alone. It may be significant that in the last 12 hours, a level of 2 $\mu\text{g.}$ was maintained when caronamide was given with the aureomycin, whereas without this adjunct the aureomycin level dropped to less than 1 $\mu\text{g.}$

TABLE II
Phlebitis following intravenous aureomycin therapy

Group	Number of patients	Number of injections	Mgms. per injection	Phlebitis	No Phlebitis
I	60	6-15	200 to 250	28 (mild)	32
II	35	1-5	250 to 350	0	35
III	21	15 to 76	250 to 500	21	0

tions have been made into the vein. Secondly, the amount of aureomycin which is injected into the vein appears to have some bearing on the formation of phlebitis.

The 116 patients who received aureomycin intravenously reacted in the following fashion (see Table II).

Although many of the patients who received the antibiotic intravenously showed a phlebitis, in the majority of instances the tenderness, induration and rigidity of the vessel disappeared within periods ranging from a few days to several weeks.

The whole problem of phlebitis was to some extent minimized when care was taken to attach intravenous infusions only after sharp needles were well into the veins. Another helpful point of technique was the practice of following the simple

fundamentals of intravenous therapy; *i.e.*, giving the first infusions in distal veins, later injections proximally, and varying the sites of injection by using alternate hands and arms. As a matter of fact, phlebitis has never been sufficiently serious to prevent a patient from receiving several injections. It is only the hypersusceptible individual who is unable to receive many injections. Occasionally, when numerous infusions are required, the presence of phlebitis makes continued therapy difficult or impossible.

One other complication was noted in three of the 116 patients. In one instance, the patient experienced a chill resulting in a fever of 101° within one hour after the intravenous administration of aureomycin. The chill was moderately severe and the fever lasted approximately one hour. Repetition of the infusion the next day produced essentially the same reaction in this patient and oral medication was instituted in place of the infusions. In a second patient, a similar reaction occurred, the fever going to 105° ; when intravenous medication was cautiously continued in this instance, however, no further reaction was observed and the patient was able to take a course of 15 injections of 500 mgms. each without fur-

FIG. 7

ther untoward reaction. In a third patient, who had a fever of 103° before the infusion was administered, there occurred a chill and rise in temperature to 105° four hours after the infusion. A repetition of the process on the following day made us reluctant to use further intravenous therapy, particularly since the patient was able to take aureomycin by mouth.

Aureomycin has shown little capacity to produce sensitization. Nevertheless, it must be borne in mind that it is only a matter of time before the patient is found who will show allergic manifestations to this antibiotic. While no serious reactions were encountered in our series of 116 patients, it has been noted that cessation of therapy was necessary in two instances where chills and fever followed the antibiotic infusions.

Since reactions have been so infrequent and of a relatively mild nature, we believe further investigation is warranted regarding the advisability of using an initial test dose of 50 mgms. or less in each patient, before an active therapeutic schedule is begun by vein.

CONCLUSIONS

1. The technique for administering aureomycin intravenously and indications for its use are discussed.
2. Blood concentrations and urinary excretions under several intravenous-oral and oral dosage schedules are submitted.
3. Absorption of aureomycin in the blood appears to vary with the individual.
4. It is suggested that caronamide may enhance blood levels of aureomycin and that it definitely decreases excretion of the antibiotic through the kidneys.
5. No serious toxic effects have been noted following intravenous aureomycin therapy. Only two of the 116 patients experienced febrile reactions. These reactions appeared to be of an individual nature since the same production lots failed to evoke reactions in other patients.

6. With the preparation of aureomycin now available phlebitis occurred in 30 to 40 per cent of the patients when the antibiotic was given intravenously.

7. Nausea and vomiting were not encountered as direct concomitants of intravenous therapy in this study. Gastro-intestinal symptoms were not noted even in a patient who had received 76 500-mgm. injections by vein.

8. We are of the opinion that intravenous aureomycin is a necessary mode of administration in some instances and a desirable one in others.

PURITY STUDIES ON POLYPEPTIDE ANTIBIOTICS: BACITRACIN¹

By LYMAN C. CRAIG, J. DELAFIELD GREGORY, AND GUY T. BARRY

(From the Laboratories of The Rockefeller Institute for Medical Research, New York, N. Y.)

As part of a broader study on Counter-current Distribution, the question of the purity of available polypeptide preparations has been taken up. We have found it possible to fractionate gramicidin, tyrocidine, gramicidin-S, and bacitracin samples into several different polypeptide components. In each case, except with the tyrocidine fractions which have not been studied antibiotically as yet, a variation in activity with the different components has been noted. They differ also in the amino acids which they contain as well as in the proportion of these amino acids.

Bacitracin for the most part has been furnished by the Commercial Solvents Co. We are indebted to them and to Miss Johnson and Dr. Meleney for the bioassays. Bacitracin has not proved to be the most ideal type of substance to distribute because of its tendency to give skewed curves and because of its lack of stability. In attempts to distribute it in neutral 2-butanol/water, the curves obtained were typical transformation curves. 2-Butanol/water acidified with acetic acid was much more satisfactory and showed only slight transformation during a run. A typical result is shown in Figure 1. This was made with a sample of 46 unit material. A calculated curve superimposed on the weight curve showed the latter to be somewhat skewed. An activity curve also was skewed but seemed to indicate a single active substance being present in the major component. A considerable band of low activity occurred to the right. Absorption spectrum measurement indicated mixtures in tubes 40 to 60.

An interesting feature of this distribution is that a maximum activity of 66 units was indicated. This was on a dry-weight basis when dried at 100° in vacuum. Material recovered from the main band by freeze-drying was a white, highly hygroscopic powder which had an activity slightly less than the maximum obtained from the curve.

That it had lost a certain amount of activity through denaturation on isolation was confirmed by redistribution. In this case a small percentage of material of low activity appeared on the left of the main band.

Hydrolysis in 6 N hydrochloric acid followed by paper chromatography gave spots corresponding to phenylalanine, leucine, isoleucine, cystine, valine, histidine, ornithine, lysine, and glutamic and aspartic acids. Strong evidence is thus furnished that the active principle is a polypeptide of considerable size.

At about this stage of our work certain toxic manifestations were encountered by others on the clinical side and it became desirable to have more careful chemical investigations in order to see if some closely related toxic substance could be removed by fractionation. This problem can be approached in two ways, namely, higher numbers of transfers or a change to a more specific system. We have investigated both approaches.

An all-glass apparatus of simple construction has been devised which is shown in Figure 2. This particular one contains 108 units but it would appear that this number could be extended several

FIG. 1. 85 TRANSFER DISTRIBUTION OF BACITRACIN IN 2-BUTANOL/3% ACETIC ACID

FIG. 2. GLASS COUNTER-CURRENT DISTRIBUTION APPARATUS CONTAINING 108 TUBES

fold if necessary for a specific problem. Enlarging is merely a matter of adding individual units. An interesting feature is that strong acids such as hydrochloric acid can be used.

A run on bacitracin using a system made with methanol, 0.1 N hydrochloric acid and chloroform gave the pattern shown in Figure 3. The overall aspects are not too different from those with the first system. Inactive material is shown at fractions 140 to 120 and a certain amount of foreign material is demonstrated on the left. Somewhat more inactivation was encountered during the run

FIG. 3. DISTRIBUTION OF BACITRACIN IN A SYSTEM CONTAINING CHLOROFORM, METHANOL AND 0.1 N HYDROCHLORIC ACID

than with the acetic acid system. When inactivation in acid solution occurs, the transformation products appear on the left. When inactivation in neutral or alkaline solution occurs, the products appear on the right. A hydrochloride with rather nice properties was recovered from the peak tubes.

At least one sample of bacitracin was not entirely stable in the solid state. This sample origi-

FIG. 4. COMPARISON OF THE EFFECT OF INACTIVATION IN ACID AND IN NEUTRAL SOLUTION

nally had an activity of 55 units and gave quite a good pattern, Figure 4, upper pattern, with 75 transfers and the acetic acid system. Only a small amount of inactive material on the right and left was obtained. After standing in the cold room for about nine months, the lower pattern was obtained with the same system but with the application of 490 transfers. The activity of the sample after nine months was 47 units. The fractions were recovered as usual by freeze-drying and, to our surprise and gratification, material recovered from the main band on one run had definite organization as shown in Figure 5. None of the fractions

recovered from other regions showed this organization. Furthermore, the recovered material had an activity of 60 units without further drying.

It would now appear fairly certain that this material is either a single substance or a mixture of very closely related substances. The evidence is not as rigorous as we would like because of inherent instability but at least the experience in two different systems points toward something definite on which to base future work.

Hydrolysis in boiling 6 N hydrochloric acid for 24 hours, evaporation of the excess hydrochloric acid, and distribution of the mixed hydrochlorides

FIG. 5. APPEARANCE OF PURIFIED BACITRACIN

FIG. 6. DISTRIBUTION OF THE HYDROLYSIS PRODUCTS OF BACITRACIN

in a 2-butanol/ammonium acetate system has given the pattern shown in Figure 6. The bands from right to left are a dipeptide containing phenylalanine and isoleucine; peptide material containing phenylalanine, isoleucine, and apparently ornithine; phenylalanine; leucine; isoleucine; ammonium chloride; histidine; and, finally, a mixed band containing cystine, lysine, and aspartic and glutamic acids. Redistribution in other systems has permitted further resolution of the mixed band. Spotting of every tenth fraction on a broad paper chromatogram permits ready control of the separation.

The original "valine" spot has been isolated in crystalline form from tubes 60-70 but it is different from valine. It appears to be absent from the most highly purified material. All the spots indicated by paper chromatography have been isolated in crystalline form with the correct carbon and hydrogen analysis except lysine and ornithine. In addition, peptides have been isolated. The amino acids isolated were of the *L*-, *D,L*- and *D*-configurations, as follows: *L*-histidine, partially racemic *L*-leucine, *L*-cystine and *L*-glutamic acid, *D,L*-phenylalanine, *D,L*-aspartic acid, and partially racemic *D*-isoleucine.

A COMPARATIVE STUDY OF THE RENAL DAMAGE PRODUCED IN MICE BY VARIOUS LOTS OF BACITRACIN¹

By LAWRENCE W. SMITH, FRED H. SCHULTZ, JR., WALLACE L. OTT,
AND HARTZELL G. PAYNE

(From Commercial Solvents Corporation, Terre Haute, Indiana)

In recent publications it has been suggested that bacitracin grown by the deep-tank method shows a higher degree of nephrotoxicity than the bacitracin produced by surface culture methods (1). The studies being reported were designed to compare the two types of material from a strictly objective standpoint.

EXPERIMENTAL STUDIES

Various lots of bacitracin were selected for this study on the basis of their previous clinical use and their availability. Unfortunately, many of the lots could not be employed because of confusing clinical data resulting from variable and uncertain dosage schedules, the use of several lots in the same patient and the known presence of impaired renal function in some cases prior to the institution of bacitracin therapy.

Of the surface culture type of bacitracin lots BV-112, BV-140, BV-142 and BV-144 were used. BV-112 was selected because it was one of the first production lots and the other three BV lots had all been employed clinically and were said to show little evidence of nephrotoxicity. Five lots, B-471212, B-480210, B-480512, B-480420, and B-481102, produced by deep-tank fermentation were similarly chosen for study. Lot B-471212 was one of the earliest lots produced by the deep-tank method which was employed clinically. Lots B-480210 and B-480512 were included in the study because of clinical evidence of nephrotoxicity, while B-480420 by contrast was stated to have extremely little evidence of toxicity when employed clinically. Lot B-481102 was especially prepared by the deep-tank method; a synthetic medium was used containing glutamic acid, similar to the medium described by Meloney and his associates in which the original production of bacitracin was developed by the surface culture technique.

The bacitracin was administered intravenously to mice of the same strain in accordance with the specifications set up by the FDA (October 14, 1948). These specifications require that mice weighing between 18 and 25 grams be injected intravenously with a constant volume (0.5 ml. per 20-gram mouse) within a five-second period. The following doses were injected: 50, 100, 200, 300, 400,

and 500 units per 20-gram mouse. The animals were observed for a 72-hour period. The mice receiving the three lowest doses, namely, 50, 100, and 200 units per 20-gram mouse, were under constant observation during the 72-hour period in order to obtain fresh autopsy material in the event of death. The kidneys were removed immediately after death and placed in 10% formalin. The survivors were sacrificed at the end of the experimental period and their kidneys fixed in 10% formalin. A series of 10 mice injected with saline served as the controls.

RESULTS

Evidence of gross pathology as expressed by the degree of ischemia present was noted and recorded on a four-plus graded scale at the time of autopsy. Histologic sections were made of the kidneys. These sections were stained with hematoxylin-eosin and were graded for evidence of renal changes independently (LWS) without knowledge of the gross renal classification. Very little, if any, correlation between the degree of renal ischemia grossly and the extent of renal damage microscopically was found.

In Table I the acute toxicity of the various lots of bacitracin is shown along with the biologic activity of each lot.

In Table II the incidence of microscopic renal injury in mice injected intravenously with various lots of bacitracin in dosages of 50, 100, and 200

CSC = Commercial Solvents lots

units per 20-gram mouse is shown. In general, it will be noted there is fairly good correlation between the size of the dose and the incidence of renal damage. Analysis of these data indicates that there is no evidence of statistically significant differences between the material obtained with surface culture bacitracin and deep-tank culture. Lot B-481102 prepared on synthetic medium and grown by the deep-tank-culture method appears to be the most toxic of all the deep-culture material.

In Table III the severity of the renal injury is shown for the various lots of bacitracin and the various dosage levels employed. It is apparent that there is no statistically significant difference in the various lots with the exception of Lot B-481102 prepared on synthetic medium. This is of interest in relation to the use of these various lots clinically. Lot B-480420 has been widely employed by a number of highly competent clinical investigators who have all indicated that it has shown a very low clinical toxicity. On the other hand, B-480210 and B-480512 were reported to be

too toxic for parenteral administration. The laboratory studies in mice indicate that there is very little, if any, difference in the amount of renal damage produced in these animals by the several lots of bacitracin.

Through the cooperation of Dr. Frank L. Meleney of Columbia University, Miss Barranovsky, statistician and secretary for the bacitracin study, has supplied clinical data on the patients treated with these specific lots of bacitracin. An attempt to correlate these data with the mice data is shown in Table IV.

In Dr. Meleney's interim report (2), he stated that the dosage used with CSC deep-culture material in general was higher than that employed with the original surface culture product. In comparing the clinical toxicity of these two types of material, he states, "It is true that the dosage with the CSC lots was somewhat larger except for Lot 480420, but this cannot account for all of the difference." These animal studies indicate that the dosage may well be responsible for any differences noted in degree of clinical toxicity.

DISCUSSION

Renal pathology

The renal pathology associated with the parenteral administration of bacitracin is, of course, one of the disturbing problems associated with the widespread use of this highly effective antibiotic. It is well known that bacitracin is a complex substance, presumably polypeptide in nature, containing a large number of amino acids, several of them in significant quantities in the *d* form. Evidence to date points toward the fact that bacitracin as presently constituted is a relatively pure substance and that this nephrotoxicity may well be inherent in the molecule. There are, however, some encouraging indications that this toxicity may at least be reduced materially if not entirely eliminated.

The pathology is distinctly one of lower nephron involvement. The changes are those of degeneration of the lining tubular epithelium, its subsequent desquamation and the formation of hyaline casts. This may proceed to a point where the major portion of the tubules become blocked. In most animals surviving a 72-hour period, evidence of regeneration of the tubular epithelium can be demonstrated. In a few clinical cases of terminal

infection where bacitracin therapy was employed, similar changes were observed. Some of these cases show evidence of associated renal pathology so that it is far from certain that the bacitracin has been a factor in the death of these patients. Most of these fatal cases were suffering from subacute bacterial endocarditis caused by organisms not sensitive to either penicillin or streptomycin. Preliminary observations suggest that a synergistic relationship exists between penicillin and bacitracin in infections of this type. This may open up a field of usefulness for bacitracin in dosage levels sufficiently low to permit its use in combination with other antibiotics without fear of the development of serious renal damage.

It is apparent from these comparative studies that very little correlation exists between the gross and microscopic pathologic changes in mice. It is likewise true that no correlation exists in the degree of renal change in the several mice to whom the same dose of bacitracin was administered parenterally. Similar differences in toxicity have been shown to exist in different strains of mice. Thus it would be theoretically possible to supply data relating to the LD-50 dosage which would not only be acceptable by present FDA specifications but would also meet with the tentative requirements

suggested by the clinicians if mice from a resistant strain were employed. The obvious conclusion must be reached that the mouse is an unsatisfactory test animal for nephrotoxicity.

SUMMARY AND CONCLUSIONS

Comparative studies of the nephrotoxicity of bacitracin when grown by surface and deep-tank culture are presented. No significant statistical differences in nephrotoxicity were found with the various lots of bacitracin.

A discussion of the renal pathology reveals that the lesion is one affecting the lower nephron.

In animals surviving a 72-hour period, representing the time interval required for evidence

of acute toxicity, tubular regeneration is apparent indicating that the changes are reversible.

There is so little correlation between the gross and microscopic evidence of renal pathology that it must be concluded the mouse is an unsatisfactory test animal.

CHEMICAL STUDIES ON POLYMYXIN B¹

By PETER P. REGNA, I. A. SOLOMONS, BERNARD K. FORSCHER,
AND ALBERT E. TIMRECK

(From the Research Laboratories of Chas. Pfizer & Co., Inc., Brooklyn, N. Y.)

Polymyxin is a generic term for chemotherapeutic antibiotics elaborated in fermentations of various media by strains of *Bacillus polymyxa* (1). The known polymyxin polypeptides (A, B, C, D, and E) have closely similar chemical and biological properties, and have in common L- α , γ -diaminobutyric acid, L-threonine and an unidentified C₉ optically-active fatty acid. In addition to these acids, polymyxin A (aerosporin) contains D-leucine (2). Polymyxin A, first described by Ainsworth, Brown and Brownlee, was isolated by Brownlee and Bushby, and Catch and Friedmann (3) from broth cultures by adsorption onto a suitable carbon and elution with aqueous acetone containing sulfuric acid. Further purification was obtained by converting the antibiotic to the helianthate and subsequently to the hydrochloride. Polymyxin D, which is composed of the constituents of polymyxin A plus serine, was described by Benedict and Langlykke (4) and Stansly *et al.* (5). It was purified by adsorption onto carbon after clarification of the fermentation liquors, elution with acid-methanol and precipitation with acetone. Further purification by Shepherd *et al.* (6) involved butanol extraction, fractional precipitation of the picrate and conversion to the hydrochloride. Hydrolyzates of polymyxin B (7), another basic polypeptide produced by strain CN 1419 of *B. polymyxa* (Wellcome Foundation Culture Numbers), show the presence of D-leucine and phenylalanine as well as the three constituents common to all the polymyxins.

During the course of studies on polymyxin B designed to eliminate toxic impurities and prepare high potency material, a procedure was developed involving adsorption of the active principle on cotton sodium succinate, elution with dilute sulfuric acid, precipitation of the antibiotic with 1-(4-chloro-*o*-sulfiophenyl)-5-hydroxy-3-

methyl-4-(p-(p-tolylsulfonoxo)-phenylazo)-pyrazole (Polar Yellow), liberation of the antibiotic, precipitation as its free base and conversion to the acid salt. The antibiotic was subsequently crystallized as its naphthalene β -sulfonate by a procedure described by Wilkinson (8).

The homogeneity of material from each purification stage was studied by partition chromatography on paper and by chemical and biological means. The paper partition chromatographic studies were carried out by a method similar to that described by Goodall and Levi (9) for penicillins. After developing and drying the paper strips, they were placed on the surface of nutrient agar previously seeded with *Escherichia coli* instead of *Bacillus subtilis*. In this way, the positions of the zones of inhibition established the presence of another active substance in certain polymyxin B fractions.

Crude material obtained from the cotton sodium succinate column was found to produce a histamine-like lowering of the blood pressure when injected into anesthetized cats. The histamine-like substance was removed from the polymyxin B by purification through its Polar Yellow salt. Fractions of moderately high potency (*ca.* 6500 units/mg.), obtained by a dual purification through the Polar Yellow salt, showed two spots on the chromatogram indicating the presence of an active minor component associated with the polymyxin B. When the acid hydrolyzates of each of these active materials were chromatographed, however, identical amino acid spectra were obtained.

In addition to the recognized components of polymyxin B, an unknown substance was routinely found high in the solvent band of the paper chromatogram of hydrolyzates of this material. Consideration of the R_F differences between glycine and alanine, alanine and valine, valine and leucine, and leucine and the unknown patch, 0.2, 0.15, 0.15, 0.1, respectively, led to the suggestion that the substance might be a C₇-amino acid. Consequently, the three leucine homologs RCH₂-

¹ Presented at the Second National Symposium on Recent Advances in Antibiotic Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotic Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

CHNH_2COOH were synthesized in which the R groups were $-\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3$, $-\text{CH}_2(\text{CH}_3)-\text{CHCH}_3$ and $-\text{CH}(\text{CH}_3)\text{CH}_2\text{CH}_3$. Chromatography of these known C γ -amino acids showed them to resemble the unknown patch, but none was identical with it. In a like manner, a similar sample of polymyxin hydrochloride separated into nine fractions by alumina chromatography showed that the hydrolyzates of all of these fractions were indistinguishable from the products of pure polymyxin B. The minor component produced by the strain was eliminated by adding alkali and precipitating the free polymyxin B base. After separating the insoluble antibiotic, the presence of the extraneous substance could be demonstrated by chromatographing the filtrate on paper. Materials of high biological activity purified through the free base followed by crystallization of the naphthalene β -sulfonate salt (8) showed but a single active component by partition chromatography.

METHODS

Paper chromatography. An apparatus for the partition chromatography method using paper was designed after suggestions of Consden *et al.* (10) and Goodall and Levi (9). The method of paper chromatography using ascending flow, described by Williams and Kirby (11), was adapted to the work discussed here by using the butanol-15% acetic acid-water solvent system and developing in one dimension only. Both intact materials and hydrolyzates were similarly analyzed on paper (12).

Hydrolysis of all samples was carried out by a standard procedure. The sample was dissolved in 5 N HCl (5 to 10% W/V) and heated for 2.5 hours in a sealed tube placed in a steam bath. This solution was evaporated to dryness in an open dish on a steam bath, and the residue was dissolved in water so that the stock solution prepared for chromatography corresponded to a concentration of 100 $\mu\text{g.}/\mu\text{l.}$ of intact material.

Solutions to be chromatographed were placed on spots along a line 2 inches from the edge of a sheet of Whatman No. 1 paper in amounts containing 10 to 100 $\mu\text{g.}$ of intact or 500 to 1000 $\mu\text{g.}$ of hydrolyzed polymyxin B. After drying, the sheet was suspended in the chamber, inoculated edge down, for at least one hour before starting the development, so that the paper could come to equilibrium with the atmosphere of the chamber. The lower edge of the paper was then placed in a trough containing butanol-acetic acid-water mixture and the chromatogram was developed by an ascending solvent flow for about 15 hours. The developed sheet was dried in an oven at 60° and then sprayed with a 0.25% solution of ninhydrin in acetone. Reclipping for five minutes to react in the amino acid ninhydrin color reaction and the R $_f$ values of the amino acids obtained from hydrolyzates of poly-

myxin B fractions was made with known acids and with known acids added to the test material.

Biological assay. In these studies, the method of biological assay was essentially that developed by Stansly and Schlosser (13) and modified by Benedict and Stodola (14) using *Brucella bronchiseptica*, strain NRRL B-140. A polymyxin hydrochloride, containing 6,650 units/mg., supplied by the Wellcome Research Laboratories (England), was used as a standard.

The paper chromatograms of intact materials were further examined for antibiotic activities by drying at 50°, after development, and pressing on agar plates (13" \times 17") seeded with *E. coli*. After refrigerating at 0° for two hours, the paper was removed from the surface of the agar and the agar plate was incubated at 37° for 15 hours. Active substances in certain samples were located by the zones of inhibition of the organism.

EXPERIMENTAL

Clarification of fermentation broth. Eight liters of a freshly harvested broth was adjusted to pH 2 with dilute sulfuric acid and heated at 90° C. for 30 minutes so as to coalesce the cells and thin out the mucilage. About 60 gm. of Super-Cel was added and the mixture was filtered. The clarified filtrate showed no appreciable loss of activity.

Adsorption of polymyxin on cotton sodium succinate. Cotton acid succinate (15) was prepared by dissolving 25 gm. of fused sodium acetate and 200 gm. of succinic anhydride in 1,500 ml. of glacial acetic acid and submerging 50 gm. of cotton in this solution at 100° for 48 hours. The partially esterified cotton was filtered, washed with water, with dilute hydrochloric acid and finally thoroughly with water. The cotton acid succinate was found to be a poor cation exchange medium for polymyxin. Therefore, the cotton acid succinate was converted to cotton sodium succinate by suspending the former in water and titrating with dilute sodium hydroxide to a phenolphthalein endpoint. After filtering and washing with water, the product was dried *in vacuo* at 50° for 24 hours.

Eight liters of the clarified polymyxin B broth (2,000 units/ml.) was poured into a column containing 50 gm. of cotton sodium succinate. About 40% of the original activity in the polymyxin B broth was found in the column. The column was washed with 2,000 ml. of water, then with 200 ml. in which the activity was 10% of that eluted from the column and finally with 250 ml. of 0.1 N sulfuric acid. Previous experiments had shown that

the polymyxin B eluted from the cotton sodium succinate column contained a histamine-like substance which was detected by the lowering of the blood pressure in cats.

Isolation of polymyxin B using Polar Yellow. The histamine-like substance could be removed from the polymyxin B eluate by purification through its Polar Yellow salt. Hence, the acid eluate was neutralized to pH 3.5 with sodium hydroxide and treated with 18 gm. of Polar Yellow. After stirring the precipitate for 15 minutes, the mixture was filtered, washed well with water and dried *in vacuo* at 50° for 48 hours. The dried mixture was suspended in 1 liter of a mixture of 85% acetone-15% methanol and treated with 25 ml. of a solution of triethylamine sulfate (0.45 gm./ml.) in methanol in order to convert the polymyxin B into the methanol insoluble sulfate. Af-

FIG. 1

FIG. 2

ter it was shaken for one hour, the mixture was filtered, the precipitate was washed with acetone-methanol mixture and finally with acetone. After it was dried, the cake was triturated in 500 ml. of water, filtered, and washed with water. The colorless filtrate was vacuum freeze-dried; a yield of about 75% of the active substance was obtained. The product had a potency of 5,200 units/mg. when assayed against *B. bronchiseptica* and had 2.3% ash.

Partition chromatograms of this intact material

showed a spot corresponding to the R_F value of polymyxin B and in addition the presence of a biologically active lower second patch (Figure 1A). However, the hydrolyzate of the intact material showed only the presence of the expected components (Figure 1B).

In the course of investigating the contaminant, a comparatively large amount of the material was put onto chromatographing paper as a swath instead of individual spots. After the usual 15-hour development, a very small portion of this swath was ninhydrin-treated to locate the spots. The remainder of the paper was cut horizontally so that two strips were obtained, each holding one component. The material held on each paper was eluted and hydrolyzed separately. It was found, on chromatographing the hydrolyzates, that both spots gave identical amino acid spectra (Figure 2).

Attempts to isolate enough of the active extraneous material for use in determining its contribution to the toxicity in animals were made by studying the chromatography of the substances on alumina.

Brockmann alumina was treated with 50% sulfuric acid to pH 6.0, backwashed with distilled water until the washings were sulfate-free and dried 24 hours at 100° C. The dried alumina was transferred to the column as a slurry in methanol. After the column was packed, a solution of polymyxin B hydrochloride (60,000 units/ml.) in anhydrous methanol was carefully poured into the column. The chromatogram was developed with absolute methanol, 95%, 90%, 80%, 50% methanol, water, and finally with 0.1 N and 0.5 N sulfuric acid. After the third fraction, each solution leaving the column was collected until it showed less than 500 units/ml., whereupon the chromatogram was developed with the succeeding more dilute methanol. Twelve fractions were collected; the methanol was evaporated from each and the residue was vacuum freeze-dried. The results of the column are summarized in Table I.

Portions of the first nine alcohol-developed fractions were redissolved and chromatographed intact on paper. The purest fraction (No. 1) appeared to be composed only of polymyxin B while the lowest potency fraction (No. 4) seemed to be made up mainly of the minor component produced by this strain. After going through a minimum, fractions 6, 7, and 8 appeared to be composed

TABLE I
Fractions of polymyxin B from alumina column

Fraction number	Developing solution	Potency units/mg.
1	100% methanol	6750
2	100% methanol	5350
3	100% methanol	4150
4	95% methanol	3530
5	90% methanol	4750
6	80% methanol	5750
7	80% methanol	5750
8	50% methanol	6050
9	50% methanol	3700
10	water	2040
11	0.1 N sulfuric acid	—
12	0.5 N sulfuric acid	40

mainly of polymyxin B. Further examinations showed that the hydrolyzates of all of these fractions yielded identical amino acid spectra, indicating that the two active substances are qualitatively related (Figure 1A). This evidence is based upon the relative solubilities of the active components in two solvents, and in turn, on their relative speeds on two chromatograms. There was found to be some important difference between the active substances because the lower component appears to be only weakly active biologically. The most effective technique for eliminating the second component involves the precipitation of polymyxin B as its free base. This was achieved by the use of amines, ammonia, sodium hydroxide, etc.

The purification of polymyxin B by precipitation of its free base. Thirteen grams of polymyxin B, obtained from the Polar Yellow purification, were dissolved in 200 ml. of water. To the cooled solution (0° C.) was added an aqueous solution of triethylamine until no further precipitation occurred (pH 11.0). The polymyxin-B-free base was filtered over Super-Cel, washed with ice water and finally with ether until it was free of triethylamine. The base was suspended in water and dissolved by the addition of dilute sulfuric acid (pH 2.5), and warming to 50°. It was neutralized (pH 5.5) with barium hydroxide and filtered from the barium sulfate. The clear filtrate was vacuum freeze-dried: yield 85%; potency 7200 units/mg.; ash 0.5%. The optical rotation increased from -61° to -76° ; and on chromatographing it on paper only one spot was observed corresponding to the R_F value for polymyxin B. The filtrate from the triethylamine precipitation was also vacuum freeze-dried after neutralization to pH 5.5; only about 10% of the activity was

found in this portion. Paper chromatography showed this intact material to be composed mainly of the lower active component.

Crystalline polymyxin B naphthalene β -sulfonate. This crystalline salt was prepared (8) by suspending 12 gm. of polymyxin-B-free base in 200 ml. of water, and adding a solution of naphthalene β -sulfonic acid with constant stirring to pH 5. The sulfonate was precipitated as a heavy oil. After standing, the supernatant liquid was decanted. The oil was washed three times with 150 ml. portions of water and dissolved in the minimum amount of ethanol. Additional alcohol was added until the solution appeared turbid whereupon it was allowed to stand at 5° for 18 hours. The sulfonate precipitate was filtered and washed with small portions of ethanol. It was then suspended in about 250 ml. of ethanol at 50° C. and treated with water until the sulfonate completely dissolved. The solution was stirred with 1 gm. of Darco G-60 at 50° for one-half hour and filtered. Ethanol was then added to the decolorized solution until cloudiness appeared, and the solution was allowed to cool slowly. The white, crystalline sulfonate crystallizes as very fine needles. The sulfonate was recrystallized by redissolving the crystals and repeating the procedure described above. Analysis of polymyxin B naphthalene β -sulfonate (dried *in vacuo* at 100° C. at 0.1 mm. Hg): C, 49.11%; H, 6.81%; S, 6.31%; N, 13.41%; $[\alpha]^{25}_D = -63.3^\circ$ (c, 1% in 75% ethanol in water); m.p. 235–8° C. with decomposition.

The crystalline polymyxin B naphthalene β -sulfonate was converted to the hydrochloride by suspending the sulfonate in anhydrous methanol and adding concentrated hydrochloric acid until complete solution took place. Polymyxin hydrochloride was precipitated by pouring the acidified methanol solution into six volumes of acetone since polymyxin B naphthalene β -sulfonate is completely soluble in this mixture. The polymyxin B hydrochloride, after drying, showed $[\alpha]^{25}_D = -75.7^\circ$ (c, 1% in 75% ethanol in water).

Partition chromatography on paper of the naphthalene β -sulfonate and the sulfate produced by metathesis reaction consistently showed a single component. Acid hydrolyzates of this component showed the presence of threonine, leucine, phenylalanine, α,γ -diaminobutyric acid, and a C_6 optically active fatty acid.

Acid hydrolysis of crude and crystalline materials yielded an optically active acid previously isolated and described by Catch, Jones and Wilkinson (2). After heating in concentrated hydrochloric acid, the fatty acid component was isolated by extraction with ether and distillation of the solvent. The yield of fatty acid was approximately 5% by weight of intact polymyxin of 5,000 units/mg. The crude acid was distilled *in vacuo* under nitrogen, and a clear colorless product was obtained with the following properties: b.p. 117–120° C. at 7 mm.; n 1.4307; $[\alpha]^{25}_D = +32^\circ$ (c, 1% in methanol); sp. gr. 0.93; mol. wt. (sodium hydroxide titration) 157.3. Anal. Calcd. for $C_9H_{18}O_2$: C, 68.4; H, 11.4. Found: C, 68.2; H, 11.4. Amide: m.p. 96° C. p-Bromphenacyl ester: m.p. 60° C.; $[\alpha]^{25}_D = -25^\circ$ (c, 1% in methanol). This optically active isomer of pelargonic acid has been recently shown to be *d*-6-methyloctan-1-oic acid by Wilkinson (8).

SUMMARY

A method for the recovery, purification and crystallization of polymyxin B is described in which the fermentation broth is clarified, adsorbed on cotton sodium succinate, eluted, precipitated as the polymyxin B Polar Yellow salt, converted to the free base and crystallized as the naphthalene β -sulfonate salt. Purification through the Polar Yellow salt removes a histamine-like contaminant, but does not remove a second minor active component the presence of which was demonstrated by partition chromatography on paper. The extraneous active substance is soluble in excess of base and can be separated from the insoluble basic polymyxin B. Paper chromatograms of the crystalline polymyxin B naphthalene β -sulfonate show a single component. The composition of the hydrolyzates of the polymyxin B and the minor active constituents are qualitatively related since they show the same acid spectra: Threonine, leucine, phenylalanine, α,γ -diaminobutyric acid, and a C_6 optically active fatty acid.

ACKNOWLEDGMENT

The authors wish to acknowledge the technical assistance of Mr. R. Carboni and Mr. M. Noseworthy in certain phases of this work. Acknowledgment is also gratefully extended to Dr. J. Means and his group for

the microanalyses, and to Dr. B. Sobin and his group for the microbiological assays.

LABORATORY AND CLINICAL STUDIES OF POLYMYXIN B AND E^{1,2}

By EDWIN J. PULASKI,³ HINTON J. BAKER,³ MILTON L. ROSENBERG,⁴
AND JAMES F. CONNELL, JR.⁴

(From the Surgical Research Unit, Brooke General Hospital, Brooke Army Medical Center,
Fort Sam Houston, Texas)

The antibiotics, polymyxin A B C D and E, have been described in the recent literature. Their antibacterial spectra are similar. They differ from one another in amino acid content. It is the purpose of this presentation to describe our studies of the antibacterial activity, pharmacology, untoward reactions, and clinical experience with polymyxin B and polymyxin E.⁵

IN VITRO ACTION

We found that the susceptibility to polymyxin of 78 strains of ten different genera by the tube dilution test (Table I) is marked against *Salmonella*, *Shigella*, *Klebsiella*, microorganisms of the *coli aerogenes* groups, and most importantly, *Pseudomonas*. *Brucella* and many staphylococci are moderately sensitive, while *Proteus* and hemolytic streptococci are refractory. It is of interest that a strain of *Pseudomonas*, which developed high resistance to streptomycin in three daily transfers, did not become resistant to polymyxin after 27 transfers. Size of inoculum and human serum reduced but slightly polymyxin activity. The concentration of polymyxin required to inhibit *Klebsiella* and *Pseudomonas* is not reduced significantly by the addition of subinhibitory amounts of streptomycin, aureomycin, sulfadiazine or penicillin, either singly or in several combinations. Polymyxin antagonizes the cumulative streptomycin-penicillin action on *Proteus*.

The administration of polymyxin to patients in divided doses by the intramuscular route in a daily dosage of 2 to 4 mgm. per kilogram of body weight results in blood serum concentrations of 1 to 8 μ g. per milliliter. The peak occurs 30 minutes to two hours following injection; one-half the peak level is noted at six hours, and the drug can be detected in blood serum up to 12 hours. When the injections are repeated at six-hour intervals, blood serum levels in excess of 30 μ g. per milliliter may be obtained after four doses. No cumulative increase in blood levels has been noted when the

TABLE I
Sensitivity to "aerosporin" polymyxin B

Organism	No. strains tested	Sensitivity range in μ g./ml.	Mean sensitivity μ g./ml.
<i>Salmonella</i>	5	0.08-0.3	0.18
<i>Shigella</i>	7	0.08-0.6	0.3
<i>Klebsiella</i>	5	0.16-1.2	0.48

Total	78		

drug is administered every 12 hours in a dosage of 1 mgm. per kilogram. Polymyxin is excreted in the urine less rapidly than penicillin and streptomycin. The amount detected in the first 12 hours after injection is less than 0.1% of the injected dose. After 12 hours, excretion increases progressively (Figure 1). On a dosage of 3 mgm. per kilogram of body weight per day levels in the urine range between 40 and 400 μ g. per milliliter after 24 hours of therapy.

We have noted that less than 1% polymyxin passes through Zeitz or sintered glass ultra fine filters. It is practical to sterilize urine for assay by heating the sample to 60° C. for one hour.

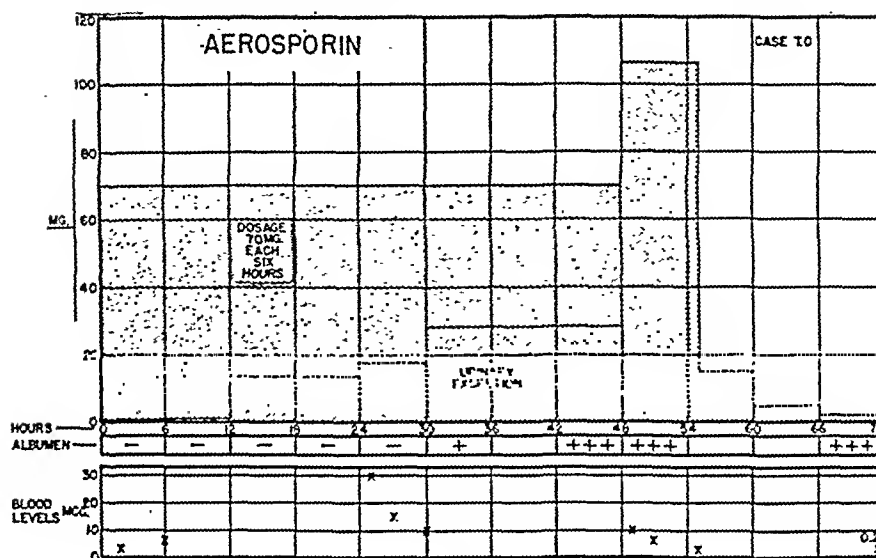

FIG. 1

Solutions of the drug are not inactivated by this treatment, but loss of potency is noted after heating to 100° C. for ten minutes. Cysteine does not appear to antagonize polymyxin activity.

CLINICAL EXPERIENCES

The therapeutic effectiveness of polymyxin has been tested at Brooke General Hospital in a series of patients with infections of the urinary tract and infections in granulating wounds. Also, the drug orally administered has been evaluated as an intestinal antiseptic in preparation of the bowel for surgery.

Twenty patients with severe urinary tract infections were treated with polymyxin intramuscularly administered over periods of one to six days in dosages of 2 to 5.6 mgm. per kilogram of body weight per day, divided in two, four, or six doses. The average, and we now believe the optimum dose, was 2.5 mgm. per kilogram per day divided in four doses for three days. Pain at the site of injection was common, but obviated by solution of the drug in 1% aqueous procaine. Nineteen of the 20 patients had extended previous trials of other chemotherapy. Ten of the 20 patients were regarded unequivocally as *benefitted*. Improvement in most instances was observed after 24 hours, as manifested by marked reduction or elimination of bacteria from the urine, regression of symptoms, decrease in fever and gross and microscopic improvement in the urine. In all patients

listed as *benefitted*, there was no bacteriological relapse up to three weeks after cessation of treatment. The most dramatic responses are obtained in polymyxin-sensitive, acute pseudomonas pyelonephritis. Usually, 12 hours after polymyxin therapy is begun the infection appears under control. The results of therapy in seven of the 20 patients are considered doubtful, either because there was little symptomatic improvement, or the urine was not rendered completely or permanently bacteria-free. In three of the 20 patients treatment was regarded as an outright *failure*. Naturally drug-resistant organisms were present in one and multiple cortical abscesses in scarred kidneys in the other two.

It is of importance that drug resistance did not develop in any of the cultures of these patients. There can be little doubt of the therapeutic effectiveness of polymyxin for the treatment of urinary tract infections produced by susceptible gram-negative bacilli, particularly acute pseudomonas pyelonephritis.

Polymyxin orally administered does not produce detectable blood levels. It exerts a rapid bacteriostatic action on most coliform bacteria, as well as on some types of cocci. Solutions of the drug were administered by mouth to 14 subjects in doses of either 200 or 400 mgm. per kilogram per day. All coliform organisms except *Proteus* were suppressed in these 14 subjects within 24 to 72 hours (Figure 2). Cocci were insignificantly reduced in

number, while *Clostridia* and *Monilia* were unaffected. Suppression of coliforms was maintained for 11 to 24 days, at which times the drug was withdrawn. Coliform organisms returned one to six days following cessation of therapy. In only one subject ingesting 2.5 mgm. per kilogram per day did the *E. coli* reappear in the stools during treatment. This organism was sensitive to 0.78 μ g. per milliliter of polymyxin. Continuation of therapy for five additional days eliminated these bacteria. All coliform organisms tested were sensitive to polymyxin before and after therapy. It is apparent at this stage of the study that 200 mgm. a day is a minimally effective dose, and that 400 mgm. is a more consistently suppressive dose.

Several granulating wounds infected with *Ps. aeruginosa* were treated by the topical application of 1% polymyxin in salt solution or carbowax base, with eradication of the organisms in all instances, except where devitalized tissue was present.

TOXICITY

No patients in this series developed any of the usual drug sensitivity reactions. No evidence of toxicity was noted following topical or oral administration of the drug. In the case of intramuscular injection, in nearly every instance neurologic disturbances were present, as manifested by paresthesias and hypesthesias mainly about the face and scalp, mild dizziness and weakness.

These symptoms usually appeared with the first dose, and persisted throughout the course of treatment. The only objective neurologic abnormality was circumoral flush. Neurotoxic symptoms disappeared in every instance within 24 hours after the last dose was administered. In no case were the symptoms severe enough to warrant cessation of therapy.

When the daily intramuscular dosage did not exceed 2.5 mgm. per kilogram, there was no increase in the blood urea nitrogen or non-protein nitrogen, nor was there any clear-cut evidence of nephrotoxicity in the form of tubular damage attributable to the drug. It is reiterated that most subjects given the drug initially had abnormal urines. Patients with normal urines did not present nephrotoxicity after three to five days on a dosage of 2 mgm. per kilogram of body weight. When the dosage was 4 mgm. per kilogram or more, tubular damage was usually noted, as evidenced by increased albuminuria, red cells, white cells, renal cells and inconstantly, granular casts in the urine. Oliguria and fixation of the specific gravity at a low level were not demonstrated in any of our cases. Urinary abnormalities produced as a result of drug therapy disappeared within four days after the drug was stopped. Both polymyxin B and polymyxin E are essentially similar in their toxic effects. We are encouraged by the relative absence of neurotoxicity in a recently tested batch of polymyxin E (EA 113).

FIG. 2

SUMMARY

Polymyxin B and polymyxin E are potent chemotherapeutic agents against susceptible gram-negative urinary tract infections, including those produced by *Ps. aeruginosa*. They are useful topically applied in eradicating these organisms in granulating wounds. Polymyxin is a potent intestinal antiseptic. Drug resistance of bacteria incident to therapy does not occur. Certain reversible neurotoxic phenomena occur following intramuscular injection of the drug, both with polymyxin B and polymyxin E, even with a single 50 mgm. dose. When the daily dosage exceeds 2.5 mgm. per kilogram, intramuscularly administered every six hours, nephrotoxicity is encountered.

Further toxicity studies on patients receiving 2 mgm. per kilogram per day intramuscularly are in progress.

PREPARATION OF A MODIFIED SUBTILIN SUITABLE FOR THE TREATMENT OF TUBERCULOSIS AND OTHER INFECTIONS IN ANIMALS^{1, 2}

By A. J. SALLE AND GREGORY J. JANN

(From the Department of Bacteriology, University of California, Los Angeles)

Subtilin is an antibiotic extracted from the cells of a particular strain of *Bacillus subtilis*.^{3, 4} It is a low molecular weight substance that dialyzes through collodion membranes, is sensitive to light and alkali, and has the structure of a peptide.

Subtilin is soluble to at least 30 per cent in salt-free acidified solution. The solubility in acid solution is markedly decreased by the presence of salt. In the presence of 0.5 to 1 per cent of sodium chloride the solubility is reduced to approximately 0.5 to 0.2 per cent. The addition of serum to an aqueous solution of subtilin produces a marked precipitation. The antibiotic is probably a basic substance giving water-soluble salts (1).

The antibacterial spectrum of subtilin (2) is similar to that of penicillin. It seems reasonable to postulate that the antibiotic might prove useful in infections caused by penicillin-fast or penicillin-resistant organisms. In addition, subtilin is effective against *Mycobacterium tuberculosis* which is not antagonized by penicillin.

The low solubility of subtilin in salt solutions and in serum is probably a desirable property in the treatment of infections caused by such organisms as the pneumococcus (3), streptococci (4), micrococci (5), the anthrax bacillus (6), etc., in which relatively small doses are required. Precipitation of the antibiotic in the presence of body fluids should slow down its elimination, thus giving

ing a more prolonged effect. However, for the effective treatment of tuberculosis the antibiotic concentration of the tissues must be maintained at a very high level. Unless the solubility of subtilin in the presence of serum can be increased it will be of limited value in the chemotherapy of tuberculosis.

EXPERIMENTAL

The solubility of the antibiotic may be improved considerably as follows: 1. Dissolve 1.5 gm. of subtilin in 50 ml. of 20 per cent urea in distilled water; 2. dissolve 0.1 gm. of pectin in 50 ml. of distilled water; 3. mix 1. and 2. and let stand overnight at room temperature for a precipitate to settle out. Centrifugate the mixture and decant the clear supernatant liquid. This clear liquid contains subtilin that is soluble in serum in all proportions and may be administered without any further treatment.

The injection of unmodified subtilin subcutaneously resulted in the formation of very hard nodule-like deposits under the skin. The subtilin was apparently largely precipitated. Sometimes these deposits produced an ulceration of the skin followed by discharge of the insoluble subtilin. Obviously, not many injections could be given. The addition of urea to a solution of subtilin increases its solubility and prevents precipitation of most of the antibiotic in the presence of serum. The pectin precipitates out that portion of the subtilin that is not soluble in the presence of serum. The removal of the precipitate gives a serum-soluble subtilin that does not produce nodule-like deposits when injected subcutaneously but is completely absorbed.

The project on the chemotherapy of tuberculosis has been under way for a period of approximately three years. At least 15 experiments have been completed involving a total of over 700 guinea pigs. The work has involved proper dosage, number of doses daily, route of injection of subtilin, and preparation of subtilin before injection.

¹ Presented at the Second National Symposium on Recent Advances in Antibiotics Research held in Washington, D. C., April 11-12, 1949, under the auspices of the Antibiotics Study Section, National Institutes of Health, Public Health Service, Federal Security Agency.

² This work was aided by a grant from the Antibiotics Study Section, National Institutes of Health, United States Public Health Service, Bethesda, Maryland.

³ The culture was originally obtained from Dr. N. R. Smith of the Bureau of Plant Industry, United States Department of Agriculture, Washington, D. C.

⁴ The subtilin used in these experiments was kindly supplied by the Western Regional Research Laboratory, Albany, California.

In most experiments a total of 48 guinea pigs were used weighing approximately 500 gm. each. The animals were infected subcutaneously with 0.3 mg. each of *Mycobacterium tuberculosis* H37Rv grown in Proskauer and Beck's synthetic medium, then divided into four groups. Group 1 animals received subtilin alone; group 2 received streptomycin alone; group 3 received a mixture of subtilin and streptomycin; and group 4 animals served as controls. Treatments were commenced generally the same day that the animals were infected. The antibiotics were injected subcutaneously three times a day at 9 a.m., 3 p.m., and 9 p.m. for 42 consecutive days (six weeks). The results of only the last three experiments are reported here.

Control Guinea Pigs. Animals in this group were inoculated with *Mycobacterium tuberculosis*

H37Rv but not treated. They served as the controls. The results are given in Table I. The method of designation of the degree of infection in this and in subsequent tables is as follows: 0 = no macroscopic lesions; + = very slight infection; ++ = more pronounced infection; and +++ = heavy infection. With a few exceptions animals in this group showed pronounced to heavy infections in the liver, lungs, or spleen. A large nodule was present at the site of the original infection.

Animals Treated with Streptomycin. Twenty-six guinea pigs were treated with 9000 units of streptomycin per day (three injections) over a period of six weeks. With a few doubtful exceptions no macroscopic lesions were noted. Animals

appeared normal except for a small nodule at the site of infection.

On the other hand, a similar number of infected animals treated with 2400 units of streptomycin per day exhibited an entirely different picture. The results are reported in Table II. Five of the animals were macroscopically negative. In the others the antibiotic produced only a suppressive effect. Lesions were present in the liver, lungs, or spleen.

Animals Treated with Subtilin. A group of guinea pigs were treated with 22 mg. of subtilin per day (three injections). The results are recorded in Table III. One-half of the animals were treated with a lot of subtilin that exhibited a low tuberculostatic effect; the other half were treated with a quantity of subtilin that showed a high tuberculostatic action. Of the 11 animals in the

latter group, five were macroscopically negative. The remaining six exhibited very light infections indicating a pronounced suppressive effect.

Animals Treated with a Mixture of Streptomycin and Subtilin. In this series the animals were treated with both antibiotics. In the earlier experiments the antibiotics were injected separately. In the later experiments it was found that the two antibiotics could be mixed and given in one injection. The results are reported in Table IV. It may be seen that the animals responded excellently to such treatment. Of a total of 26 animals, 21 were macroscopically negative; the remaining five animals exhibited extremely light infections.

DISCUSSION

Subtilin is not a uniform compound but contains a fraction that is insoluble in serum. The removal of this insoluble fraction gives a product that is soluble in serum in all proportions.

It is felt that emphasis should be placed on the results reported in Table III. They indicate that subtilin might well be used alone for the treatment of tuberculosis. It is seen that the animals treated with a good lot of subtilin responded favorably to treatment and that no toxic manifestations were evident despite the massive doses administered. The low toxicity of subtilin *in vivo* is in keeping with its results *in vitro* where it was found that the antibiotic was approximately 20 times more toxic to *Micrococcus pyogenes* var. *aureus* than to

living embryonic chick heart tissue fragments (7).

A number of subtilin samples, prepared and purified at the Western Regional Research Laboratory, United States Department of Agriculture, have been tested for their tuberculostatic potencies. In view of the known impurity of the antibiotic, the samples showed great variation in their action on the tubercle bacillus. However, subtilin prepared and purified by a method which would give consistently good results might well be used in the treatment of tuberculosis.

Another point which we should like to stress is that the antibiotic may be combined with streptomycin in the chemotherapy of tuberculosis, thereby decreasing the dosage of the latter. By so doing, toxic manifestations of streptomycin may be considerably reduced or perhaps eliminated completely.

ACKNOWLEDGMENT

The authors wish to express their kindness to Mr. Michael Ordanik for technical assistance during the progress of this work.

ABSTRACTS

Penicillin

Factors Affecting Paper Chromatography of Penicillins.

MARVIN J. JOHNSON. Department of Biochemistry, University of Wisconsin, Madison, Wisc.

Although penicillin chromatography has been used to illustrate the factors discussed, much of the material is equally applicable to chromatography of other antibiotics.

The performance of an analytical chromatogram may be expressed in terms of its resolving power which in turn may be defined as being inversely proportional to the percentage difference in distribution coefficient necessary to produce a given separation of two components. The resolving power of a chromatogram for any pair of components is calculable if certain basic data are at hand. In other words, it is possible to predict whether a given set of chromatographic conditions will effectively separate a given pair of components, or at least to predict under what conditions separation is most likely to occur.

Variation in pH constitutes a convenient method of changing the rate of migration of all components by an equal factor. Change of solvent usually produces an analogous effect. By proper choice of pH and solvent, any desired component may be brought to the region of maximum resolution in the chromatogram. Variation in amount of mobile phase allowed to flow causes a change not only in the position of the components on the chromatogram, but also in their degree of separation. By changing both pH and amount of solvent flow, enhanced resolution may be obtained. Unless excessive flow rates or other faulty techniques are used, the number of theoretical plates realized per unit length of column is probably largely determined by the type of paper chosen.

Comparative Penicillin Assays. D. K. KITCHEN, E. W. THOMAS, C. R. REIN, and W. E. CRUTCHFIELD, JR. Bristol Laboratories, Inc., New York, N. Y.

The purpose of this study was to establish, from a practical standpoint, the degree of accuracy and consistency inherent in two assay procedures. Known standards of crystalline Penicillin G in three concentrations (approximately 3.0, 0.3 and 0.03 units/cc.) in three diluents (gelatine, phosphate buffer and human serum) were prepared. These were assayed by the "cup plate method" using *Sarcina lutea* as test organism and the "serial dilution method" using *B. subtilis* as test organism. Fifteen duplicates were performed using each method at each concentration. All assays were performed immediately following the preparation of the standards from the dry stable salt. The results are graphically portrayed in a table giving numerical values obtained on average blood levels and the percentage of standard measured by each method. A chart depicting individual assay distribution points has been prepared. This demonstrates clearly that under the conditions studied it is apparent that the "cup plate" assay procedure is more accurate than the "serial dilution" method.

The Pathogenesis and Pathology of Airborne Mouse Pneumonitis Virus Infection in Mice. II. The Effect of Penicillin and Sulfadiazine on the Developing Lesion. CLAYTON G. LOOSLI. Department of Medicine, University of Chicago, Chicago, Ill.

Fatal pulmonary infections can be produced in mice by allowing them to breathe air for one hour in a 60-liter chamber into which is atomized 4 cc. or more of 10^4 dilution of mouse lung suspension of mouse pneumonitis virus. Animals die of extensive pulmonary consolidation from ten to 16 days following exposure. Intranasal inoculation (0.05 cc. of virus suspension) kills mice in 48 hours. There is evidence microscopically that the virus vesicle develops extracellularly on the surface of the alveolar walls as well as intracellularly in the bronchial epithelial cells.

Total daily doses for 16 days of 2,000 units of Penicillin G in saline given subcutaneously (500 units per 0.1 cc. dose) immediately before or after airborne inoculation suppressed the development of the lesion but did not sterilize the lungs. Seventy-two hours after discontinuing penicillin, gross lesions were present and large amounts of virus could be obtained from the lungs of the treated animals. Sulfadiazine (8 mgm. per day in four doses, 0.1 cc. subcutaneously) sterilized the lungs after seven days of treatment.

Penicillin G (8,000 units per day in 8 doses, 0.1 cc. subcutaneously) given at three-hour intervals following intranasal inoculation altered greatly the developing virus vesicle as seen microscopically. Sulfadiazine (20 mgm. per day) prevents the development of the virus vesicle.

The above observations on the effect of antibiotics on the mouse pneumonitis virus may be of value in further elucidating the fundamental nature of the viruses of the *psittacosis lymphogranuloma* group. Detailed reports of the above studies will appear later.

Hypersensitivity to Penicillin. J. F. WALDO and JEANNE T. TYSON. Department of Internal Medicine, College of Medicine, University of Utah, and Salt Lake General Hospital, Salt Lake City, Utah.

In certain instances it has been possible to demonstrate by passive transfer, employing the Prausnitz-Kustner technique, a circulating antibody to penicillin. This passive transfer was best accomplished from severely reacting subjects during the most active phase of the reaction. The antigen employed for the passive transfer was crystalline Penicillin G dissolved in saline.

By binding crystalline benzyl penicillin (Penicillin G) to pure human albumin and injecting this in rabbits an antibody has been produced which gives a moderately strong complement fixation reaction with the albumin-penicillin mixture after all reactivity to human albumin has been absorbed. Penicillin alone, administered to the rabbit, has failed to produce such an antibody. Some evidence has also been obtained which indicates that when penicillin is bound to human albumin, the reacting anti-

genic product behaves in the manner of a mixed antigen while the human albumin used in the experiment behaves in the manner of a pure antigen. Quantitative studies of this antigen-antibody system seem to substantiate this.

Comparative studies with n-heptyl penicillin (Penicillin K) are now in progress because it is believed by most observers that this penicillin is more completely bound to the protein than is benzyl penicillin. If this is true the antibody reaction should be more marked.

Inasmuch as it is known that penicillin is bound *in vivo* to albumin it seems reasonable to suppose that when penicillin is administered to man, the penicillin haptene coupled to albumin *in vivo* constitutes an antigen which leads to the production of an antibody specific for this haptene group. This might well account for the penicillin sensitivity reactions observed in man.

The Jarisch-Herxheimer Reaction in Early Congenital Syphilis. A Study of 93 Patients Treated with Penicillin Alone. HAROLD A. TUCKER¹ and OSVALDO A. PARDO.² U. S. Public Health Service and the Johns Hopkins Venereal Disease Research and Post-Graduate Training Center, Baltimore, Md.

Between 1943 and March, 1948, 93 children under three years of age were diagnosed as having untreated early congenital syphilis at the Johns Hopkins Hospital. Each was treated with penicillin as the sole antisyphilitic agent. A fever of 38° C. or greater in a previously afebrile patient, occurring from four to 36 hours after the start of penicillin administration and lasting less than 36 hours, was interpreted as a febrile Jarisch-Herxheimer reaction. Forty-five children (48.5 per cent) showed such reactions.

No relationship between incidence and magnitude of the reaction and age, race, sex, type of congenital syphilis, serologic titer or outcome, was observed. The type of penicillin (*e.g.*, amorphous or crystalline G) likewise did not appear to be a factor nor, within the range of 250 to 7,690 units/kg. of body weight, did the gravimetric dosage given. When it occurred, the reaction seemed to be entirely analogous to that seen in the adult with early acquired syphilis.

Five of the 93 children died and in each case prematurity, malnutrition, general debility and/or intercurrent disease were complicating factors. None of these deaths was believed by us to be directly attributable to the Jarisch-Herxheimer reaction. It was our feeling that the outcome was largely dependent upon the general condition of the patient, and that a successful result depended as much, or more, on general pediatric management as upon the type or amount of syphilotherapy employed.

Treatment of Various Infections with a Single Injection or Injections at Five Day Intervals of 300,000 Units (1 cc.) Procaine Penicillin in Oil with 2 per cent W/V Aluminum Monostearate. WALTER KURLAND and HAR-

OLD L. HIRSH. Georgetown University Medical Division, Gallinger Municipal Hospital, and the Department of Medicine, Georgetown University School of Medicine, Washington, D. C.

The present study was undertaken to determine whether common mild and moderate infections can be adequately treated by a single 1 cc. dose of procaine penicillin in oil with aluminum monostearate containing 300,000 units.

Included in this series were 41 patients with scarlet fever. In all but three, throat cultures became negative within 48 hours after administration of the penicillin. These three became negative after 72 hours. One of the three became positive again after 96 hours and persisted as a carrier until a second dose was given on the 11th day, whereupon he again became negative. Two of the 41 patients developed complications. One developed a serous meningitis on the seventh day which cleared rapidly within several days. Another patient developed a purulent otitis media on the tenth day, after having been taken home inadvertently on the preceding day by her parents. Temperatures fell to within normal limits within 48 to 72 hours in all patients except three, and in two additional patients therapy was given. It was strongly suspected that one of these patients did not receive his initial dose and the other required sulfonamides.

Of the 82 patients with lobar pneumonia, three failed to respond adequately to the single injection but recovered following the administration of additional doses, and in two suppuration in the pneumonic area developed which was treated with intensive antibiotic and chemotherapeutic drugs. Seven patients, all with serious complications, died: delirium tremens (2); severe cardiac disease (2); diabetic acidosis (1); asthma with purulent bronchitis and an acute lung abscess at another site (1); and possible renal disease (1).

Successful results were obtained in nine patients with otitis media; one with a hemolytic streptococcus pharyngitis; one with a Vincent's infection of the throat, and three with cellulitis.

Delayed Administration of Oral Penicillin¹ as Prophylaxis for Gonorrhea. V. W. H. CAMPBELL,² WILLIAM J. DOUGHERTY,² and C. E. CURTIS.³ Communicable Disease Control Section, Department of the Navy, Washington, D. C.

The study of the prevention of gonorrhea by Eagle *et al.* has indicated that the utilization of per oral penicillin, 100,000 to 250,000 units, within a short time after venereal exposure is highly effective in the prevention of gonorrhea.

The operation of a Naval Force in an area where high venereal disease rates prevailed afforded the opportunity to conduct further study designed to determine the feasibility and efficiency of prophylaxis by oral penicillin given 12 to 24 hours after exposure to venereal disease.

¹ Department of Bacteriology, University of Southern California School of Medicine, Los Angeles, California.

² Department of Dermatology and Syphilology, University of Habana, Cuba.

³ The penicillin tablets and placebos used in this study were furnished by Commercial Solvents Corporation.

² Commander, MC, USN.

³ Lieutenant, MSC, USN.

Two thousand and eighty men participated in the study. One thousand and fifty-nine men in the experimental group experienced 1,833 liberties and 2,625 exposures, resulting in nine cases. This yielded a rate of 4.75 cases per 1,000 liberties and 3.4 cases per 1,000 exposures.

One thousand and twenty-one men in the control group experienced 1,891 liberties and 2,686 exposures, resulting in 22 cases of gonorrhea. This yielded a rate of 11.6 cases per 1,000 liberties and 8.2 per 1,000 exposures.

The experimental group received 200,000 units of sodium Penicillin G by mouth following a mean elapsed interval between exposure and penicillin prophylaxis of 15 hours. The variation about this mean was approximately 3.5 hours.

Contrasted to the study reported by Eagle *et al.*, in which the probable elapsed time of two hours between exposure and per oral penicillin was reported, this study indicates that within an increasing interval between exposure and utilization of the tablets, the prophylaxis efficiency of per oral penicillin is reduced.

Use of Penicillin in Oral Vincent's Infection as a Means of Rapidly Controlling "Epidemics." J. LOOBY¹ and CARL A. SCHLACK.² Naval Medical Research Institute, National Naval Medical Center, Bethesda, Md.

This project (X-345) was approved by the Chief of the Bureau of Medicine and Surgery, U. S. Navy, 15 March 1944. Oral color photographs were used as controls and, in all, 107 patients were treated. Fifty-two patients were given 25,000 units of penicillin intramuscularly every three hours until 100,000 to 200,000 units had been injected. Fifty-five patients received topical application of 250 units per cc. saline solution; 10 cc. sprayed on tissue and 3 cc. swabbed on lesions (swab remained in mouth for 10-20 minutes). No other form of treatment was employed (no scaling, mouth washes, oral hygiene, change of habits [dietary or otherwise]). Of those receiving intramuscular injections, 50 showed disappearance of painful symptoms and improvement in tissue appearance in 24 to 48 hours; one reached this stage in 72 hours, and one was indeterminate. Of the groups receiving topical application, 44 showed improvement in 24 to 72 hours, nine were indeterminate, and two failed to improve. The majority in both groups showed reduction in bacteriologic smear positives for Vincent's spirochetes and fusiform bacilli after treatment.

It appeared that the intramuscular injection of penicillin was more effective than the topical application as a means of rapidly controlling "epidemics" of oral fusospirochetosis (Vincent's infection).

Further Observations on Protection against the Lethal Effects of Bacterial Endotoxin by Penicillin and its Impurities. WALTER D. HAWK, WILLIAM H. ANDERSON, and C. PHILLIP MILLER with the technical assist-

ance of BARBARA BOWDEN. Department of Medicine, University of Chicago, Chicago, Ill.

Previous findings regarding protection of mice against the lethal effect of certain bacterial toxins by the intraperitoneal administration of penicillin and its impurities have been enlarged and several related questions have been answered.

1. This means of protection, which has proved effective against the endotoxins of meningococcus, gonococcus, *Salmonella aertrycke*, and a number of other Gram-negative organisms, has been shown to be without effect against exotoxins obtained from *Staphylococcus*, *Cl. botulinum* and *Cl. tetani*.
2. Administration of a number of drugs hitherto untested (streptomycin, aureomycin, the anti-histaminics, etc.) has provided none of the protection shown with penicillin.
3. Preliminary administration of sublethal doses of homologous endotoxin (as described by Cantoni) provides only slight protection as compared with that obtained with impure penicillin. Colchicine with penicillin provides no protection.
4. The administration of adrenal cortical extract with penicillin or adrenal cortico-trophic hormone with penicillin provides only slight protection.
5. The intravenous administration of penicillin and its impurities is of some benefit but cannot be carried out satisfactorily because of the toxicity of the drug in its present unpurified state.
6. Several new means of preparing the "penicillin impurities" have been tested. It has been shown that the protective factor(s) in this material is readily obtained by extraction of the "spent beer" discarded after commercial extraction of penicillin from the fermented liquor.
7. A rapid and economical method of bio-assay of the protective factor has been developed.
8. The "penicillin impurities" used in this work have been shown regularly to contain large amounts of the "enhancement factor" described by Welch, Hobby and others. Unusual prolongation of penicillin blood levels following the administration of these materials could not be demonstrated in our experiments.

Certain Effects of Antibiotics on Animal Tissue Homogenates and Subcellular Elements. KENT WRIGHT and DEAN BURN. National Cancer Institute, Bethesda, Md.

These studies were carried out using aerobic methylene blue reduction and Warburg techniques. For the methylene blue reduction studies, mouse livers were homogenized with a mortar and pestle in 0.01 M phosphate. The substrates were malate, pyruvate, acetate, lactate, alcohol, oxalacetate, fumarate, and citrate at 0.01 M and in each case 4 ppm methylene blue. Purified penicillin, a yellow component of crude penicillin, increased the reduction time 100 per cent above that of the control. With malate present, the effect was even more striking. Penicillin and streptomycin increased the reduction time as much as 50 per cent in concentrations of 1,000 ppm or higher. The

¹ Commander, DC, USNR (inactive).

² Commander, DC, USN.

same effects were observed with acetate and in the case of streptomycin also with ethyl alcohol. For pyruvate none of the antibiotics inhibited methylene blue reduction. Other antibiotics studied were subtilin and siderophilin.

The tumors used were the S-91a grown on C mice and the C₃HBA on C₃H mice. The time of reduction of methylene blue by the S-91a tumor fractions was one-fifth the time required by liver homogenates. This was further affected by penichromin (> 1,000 ppm) to the extent of 100 per cent.

The particulate fractions were prepared by homogenizing the tumors in 0.85 per cent saline, filtering through glass wool, and centrifuging at 26g for separation of the nuclei followed by 9,000g for the mitochondria.

In the case of the S-91a tumor homogenates, the manometric studies showed inhibition of succinate oxidation by penichromin at 500 ppm of 50 per cent and no effect by actidione, aspergilllic acid, or subtilin.

For the mitochondrial fraction using the C₃HBA tumor in the presence of cobalt at 50 and 20 ppm, the Q_{o2} of 4.6 was decreased to 1.4 and 3.1 respectively. Similar results were obtained with penichromin.

Thus some antibiotics have a striking effect on the enzymes of animal tissues at the subcellular level while some do not except at very high concentrations.

Studies on Bromine-Oxidizable Sulfur-Containing Compounds in Mold Metabolism. CLAUDE H. PLUMLEE and ARTHUR L. POLLARD. Department of Bacteriology, The University of Tennessee, Knoxville, Tenn.

In the course of a quantitative study of the sulfur metabolism of *Penicillium chrysogenum* Q-176 it was found that sulfur compounds oxidizable to sulfate by bromine water were formed and that they accounted for over one-third of the organic sulfur in the culture filtrate. The organism was grown on Czapek-Dox medium containing sulfur only in the form of magnesium sulfate. It was certain, therefore, that all forms of organic sulfur were synthesized by the organism. Other investigators have found that the sulfur in thiamine, biotin, cysteine, cystine, and glutathione is not oxidizable to sulfate by bromine water. Apparently this oxidation is confined to very specific configurations of the molecule such as are found in the xanthogenic acids and in thioacetamide. It is not clear whether such compounds are intermediates in the process of penicillin synthesis or whether they are formed in equilibrium with other sulfur compounds, one of which is penicillin.

The subject is of considerable interest because of the great number of physiologically active sulfur compounds and the wide variation of activity with molecular configuration. Thioacetamide, for example, has been shown to be readily utilized by *Aspergillus niger* whereas some of the xanthates, thiuram derivatives and disulfids are highly fungistatic.

Streptomycin

The Disappearance of Streptomycin-Resistant Bacteria During or After Streptomycin Therapy. MORTON HAX-

BURGER and JEROME R. BERMAN. Department of Internal Medicine, University of Cincinnati, Cincinnati, Ohio.

Though the appearance of streptomycin-resistant bacteria during the course of streptomycin therapy has been abundantly demonstrated, less attention has been paid to the ultimate fate of these resistant forms. Observations upon this problem have been made during a study of the development of resistant coliform bacilli in the stools of patients given intramuscular streptomycin for tuberculosis or oral streptomycin for intestinal tract infections.

Suspensions of 0.5 cc. stool in 5 cc. saline were streaked on each of two eosin-methylene blue plates, one containing 100 gamma streptomycin per cc. and the other no streptomycin. Colonies were picked from representative plates for more accurate determination of streptomycin sensitivity in a serial dilution test.

In no case were coliform bacilli recovered prior to the administration of streptomycin resistant to more than 2.5 gamma per cc. When streptomycin-resistant forms did appear, 156 to more than 2,500 gamma were necessary for growth inhibition.

In five cases (three treated orally and two intramuscularly) where streptomycin was discontinued after the appearance of highly resistant variants, the resistant strains were replaced by sensitive forms. This process started very soon after the cessation of treatment. Whereas during treatment resistant forms were recovered from both the eosin-methylene blue plate containing streptomycin and the plate which contained none, these forms practically disappeared from the latter after treatment. Days or weeks later, even the plate containing streptomycin failed to show growth when stool suspensions were streaked upon it.

In two cases of tuberculous peritonitis where improvement occurred during treatment, the resistant variants disappeared while the patients were still receiving streptomycin.

Evaluation of Oral Streptomycin in Specific Enteritis in Infants and Children. SIDNEY ROSS, E. CLARENCE RICE, FREDERIC G. BURKE, and JOHN A. WASHINGTON. Children's Hospital, Washington, D. C.

Thirty-four cases of shigella enteritis were treated with oral streptomycin. Twenty-five of the cases were acute while nine were carriers. The average dose of streptomycin orally was 400 mgms. every four hours. The duration of treatment ranged from seven to 19 days with an average of 10.7 days per patient. In the acute cases the positive stool cultures became negative rapidly generally within an average of one to two days. In the carrier group none of the 12 cases showed positive stool cultures within 24 hours following initiation of therapy. An average of 11 negative stool cultures was obtained on each patient before he was considered cured. Once the stool culture became negative, no cultural reversals were noted during the hospital stay. In five of the cases, however, there was a recurrence of positive stool cultures within one month after discharge from the hospital.

Clinically, the improvement was commensurate with the salutary effect observed bacteriologically.

Eight cases of salmonella enteritis in infants and children were treated with streptomycin in large doses ranging from 2.4 to 3.6 gms. per day. Three of the patients received the drug orally only while the other five were given the antibiotic both orally and intramuscularly. In spite of the demonstrated sensitivity of the organism to streptomycin *in vitro* in each case, only one of the eight cases was rendered permanently free of the organisms. In the other seven cases an inhibitory effect on both the salmonella organism and the normal stool flora was observed during the period of drug administration; however, within three to eight days after streptomycin was discontinued, the pathogen reappeared in the stools. No significant increase of streptomycin resistance during the course of therapy was noted in any case.

The Treatment of Tuberculosis with Small Doses of Streptomycin. BERNARD MILLOFF, SOL KATZ, and HAROLD L. HIRSH. Georgetown Medical and Tuberculosis Divisions, Gallinger Municipal Hospital, and the Department of Medicine, Georgetown University School of Medicine, Washington, D. C.

Although the value of streptomycin in the treatment of tuberculosis has been rather fully established, a complete appraisal of dosage and duration of treatment has not been ascertained. Therefore, we have treated a variety of tuberculous infections with small doses of streptomycin. All patients received one-half gram per day in one dose except four with miliary tuberculosis who were given one-half gram twice a day. This dose schedule was selected on the supposition that with the smaller doses the development of organism resistance is not increased and streptomycin toxicity is decreased.

The following results were obtained:

Miliary—5—all developed meningitis and died;
Bronchial—4—favorable response after prolonged therapy;
Pericarditis—2—one favorable response, one failure;
Pleurisy with effusion—1—no response;
Peritonitis—2—relapse after improvement;
Mediastinitis—1—favorable response;
Adenitis—3—no response;
Osseous—4—no response;
Draining sinuses—7—apparently healed.

In two patients with tuberculous bursitis incision and drainings while under streptomycin therapy resulted in healing.

In forty-two patients with 80 operations, which included thoracoplasty, lobectomy and pneumonectomy, no tuberculous spreads occurred with the use of one-half gram per day in a single injection for seven days pre-operatively and post-operatively.

Streptomycin in doses of one-half gram per day would appear to be definitely effective in the treatment of bronchial tuberculosis and draining sinuses. It would also be recommended that this same dosage be used in the prevention of tuberculous spreads in the surgery of tuber-

culous patients. In those tuberculous infections where streptomycin is generally effective, smaller doses are apparently as good.

Incidence of Vestibular Dysfunction Following Intramuscular Administration of Various Doses of Dihydrostreptomycin. SOL KATZ, WALTER KURLAND, and HAROLD L. HIRSH. Georgetown Medical and Tuberculosis Divisions, Gallinger Municipal Hospital, and the Department of Medicine, Georgetown University School of Medicine, Washington, D. C.

Recently a reduced streptomycin compound, dihydrostreptomycin, has been developed which appears to be less neurotoxic in preliminary studies in animals and humans.

On the basis of these data a study of dihydrostreptomycin was undertaken. Included in our series are 26 patients. Five patients received 1 gram per day in divided doses every six hours and none have developed evidences of vestibular dysfunction after 13 weeks of therapy. However, of three patients on 0.5 gram every six hours (2 grams per day) for 13 weeks one showed vestibular dysfunction after the sixth week of therapy and the other after the ninth week.

Doses of 3 grams per day (0.75 gram every six hours) were administered in eight patients. Three were treated for 13 weeks and one for 60 days without evidences of impairment of vestibular function. Two demonstrated impairment after six and eight weeks of treatment, respectively. In one, vestibular dysfunction appeared after the first treatment week and in another, a 13 year old boy, after the seventh week.

Three patients were given 3 grams per day in doses of 1.5 grams every 12 hours for a period of four to five weeks. Two developed vestibular impairment after the first and second weeks of therapy, respectively. One was 69 years of age and the other had unilateral dysfunction from a previous course of 150 grams streptomycin. One patient received 1 gram of dihydrostreptomycin for 14 days followed by 3 grams for 18 days. He showed no impairment of vestibular function.

Five patients received 1 gram every six hours for 7, 35, 35, 60 and 60 days, respectively, without impairment of vestibular function. Vestibular dysfunction was noted in one patient on this dosage-schedule after the fourth week of therapy.

The Therapeutic Use of Antibiotics: Comparative Activities, Synergism, and Resistance

The Summation of Penicillin and Streptomycin Activity In Vitro and in the Treatment of Subacute Bacterial Endocarditis. WILLIAM C. ROBBINS and RALPH TOWNSETT. Department of Medicine of the New York Hospital-Cornell University Medical College, New York, N. Y.

Despite the fact that the summation of action of two drugs is an established principle of pharmacology, few examples of unquestionable summation of the action of

two antimicrobial agents in the treatment of infection in man are to be found.

The therapeutic effectiveness of penicillin in subacute bacterial endocarditis has resulted in the arrest of the infection in all but 10 per cent of cases. The majority of this latter group of patients are infected with *Streptococci* of the Lancefield serologic Group D, the most important members of which are commonly termed *Streptococcus fecalis* and *Streptococcus zymogenes*. These enterococci are highly insensitive to penicillin, and although temporary suppression of the endocarditis caused by these organisms is readily attained with its administration, relapse almost invariably ensues after the penicillin is discontinued. Enterococci also exhibit considerable resistance to streptomycin, and results of the treatment of enterococcal endocarditis with streptomycin, though of limited extent, have been only slightly better than those achieved with penicillin.

A study has been made of the individual and combined actions of penicillin and streptomycin *in vitro* on strains of *Enterococcus* and *Streptococcus viridans* isolated from patients with endocarditis. It has been observed that the two drugs act as adjuvants in inhibiting growth of all strains studied, total summation of partial effects occurring throughout a wide range of concentrations of each constituent drug. For example, complete inhibition of growth was achieved with a mixture containing one-fourth the inhibitory concentration of penicillin plus three-fourths of the inhibitory concentration of streptomycin, or with a mixture containing one-half the inhibitory concentration of each. In some instances inhibition has occurred with constituent drug fractions which total less than one, indicating an effect greater than summation.

Six patients with persistent enterococcal bacteremia, five of whom had endocarditis, have received six million units of penicillin and 2 grams of streptomycin, or its dihydro derivative, daily. Two patients received the combined therapy only terminally, but four completed a course of four to eight weeks of this therapy. Bacteremia was promptly reversed and there was sustained clinical improvement in all four. All but one patient have been followed for periods of from six to 12 months and none has relapsed.

The uniformly good results with these patients have been in striking contrast with the previous experience with the use of either drug alone in these infections, and suggest the operation of a summation effective *in vivo* comparable to that observed *in vitro*. Experiments are now in progress which indicate that the summation of penicillin and streptomycin may apply to organisms other than penicillin-resistant streptococci, and that summation may occur with other antibiotic combinations. The use of combinations of antimicrobial drugs may offer an effective method of achieving permanent arrest of infections which can now only be suppressed by the use of one drug alone.

Pharmacological Studies on Actidione. ANNESS GOTH and HARRIS J. ELLERSON. Department of Physiology

and Pharmacology, Southwestern Medical College, Dallas, Texas.

Actidione is characterized by a marked growth inhibitory activity against certain fungi and by a considerable species variation in its toxicity to mammals. The purpose of the present study was twofold: to demonstrate inhibitory blood levels in various species of mammals following the injection of actidione and to study the nature of its toxicity.

A solution of crystalline actidione was injected intraperitoneally into rats, guinea pigs, and dogs. The citrated plasma of these animals was tested by a serial dilution method in tryptosephosphate broth for inhibitory activity against *Saccharomyces pastorianus* ATCC2366.

After the injection of 1 to 10 mg. of actidione per kg. into rats, 5 to 20 dilution units were detected in the plasma in 30 minutes. The inhibitory activity decreased somewhat in 90 minutes. The results were essentially the same in guinea pigs and dogs.

It appears from these data that actidione is absorbed rapidly from the intraperitoneal site and is not rapidly inactivated in the body.

The injection of as little as 1 mg. of actidione per kg. body weight intravenously into the dog is followed by vomiting in a few minutes. This emetic effect is prevented by nembutal anesthesia. Nausea has also been observed in humans following the injection of actidione.

Comparisons of Six New Antibiotic Agents in Experimental Infections in Mice. ELEANOR A. BLISS and PATRICIA TODD. Department of Preventive Medicine, The Johns Hopkins University School of Medicine, Baltimore, Md.

The therapeutic activities of penicillin O, aureomycin, chloramphenicol, polymyxin D, polymyxin B and Q 19 (circulin) were compared in mouse infections induced with a type I pneumococcus, a Group A hemolytic streptococcus, and a strain of *K. pneumoniae*, type A. Penicillin G and streptomycin were included as standards. Two strains of mice were employed, a mixed strain of Swiss mouse and the pure CF₁ strain. Therapy was administered by the subcutaneous route, three treatments being given at 0, 5½, and 23 hours after infection. Two or more agents were compared in each experiment, usually at three doses each. The median protective dose was estimated.

The polymyxins and Q 19 were most effective in the therapy of the *K. pneumoniae* infection; the PD₅₀ for all three was less than 1 mg/kilo per treatment. The PD₅₀ for streptomycin was 2.5 mg/kilo; for aureomycin and chloramphenicol it was 35 to 50 mg/kilo. In the treatment of the streptococcal infection, Penicillin G and O were most effective with PD₅₀'s of about 0.3 mg/kilo. The PD₅₀ of aureomycin was 4 mg/kilo while that of streptomycin was 70. The PD₅₀ for chloramphenicol here and in the pneumococcal infection could not be determined because of the limited solubility of the agent, even in 20 per cent alcohol. It was above 80 mg/kilo. In the pneumococcal infection the same order of activity pre-

ailed, with the notable exception that aureomycin was the most effective agent in the CF₁ mice. The PD₅₀ for Penicillin G in this mouse was ten times as high as in the mixed strain of mice.

The Effect of Antibiotics on the Growth of Histoplasma Capsulatum in Vitro. BEN D. CHINN and MARIO MOL-LARI. Department of Bacteriology and Preventive Medicine, Georgetown University School of Medicine, Washington, D. C.

A study was made of the effect of several antibiotics on the growth of *Histoplasma capsulatum* in vitro. *H. capsulatum* is the etiologic agent of Histoplasmosis, a disease characterized by emaciation, leukopenia, anemia and irregular pyrexia, and produces cutaneous ulcers and primary involvement of the lungs. The antibiotics used included penicillin, streptomycin, bacitracin, aureomycin, polymyxin A, aerosporin (polymyxin B) and chloromycetin.

The measure of activity against the test organism was determined by the streak method, the agar diffusion method, and the serial dilution method. Penicillin showed inhibitory effects in concentrations above 5,000 units/ml of medium (blood agar). A more marked effect was produced by streptomycin. Inhibition of growth began with 50 mg/ml of medium and only slight growth occurred beyond 200 mg/ml. Chloromycetin showed no antibiotic activity. Aureomycin and polymyxin A showed slight activity above concentrations of 20 mg/ml, but increases in the concentration beyond this amount did not produce a corresponding effect on the growth of the test organism. Bacitracin appeared to have a marked inhibitory effect on the growth of the organism in concentrations of 600 units or higher. Aerosporin had an activity similar to bacitracin, its antibiotic activity beginning with 5 mg/ml.

Among the antibiotics tested streptomycin appeared to have the greatest inhibitory action on *H. capsulatum*. The effect of some of these antibiotics in experimentally infected animals is under investigation.

The treatment of certain forms of Histoplasmosis has been very unsatisfactory; the disease is generally considered highly fatal. The possibility of antibiotic therapy appears worthy of consideration.

The Combined Action of Antibiotics and Sulfonamides in Experimental Infections. C. W. PRICE, W. A. RANDALL, and H. WELCH. Federal Security Agency, Food and Drug Administration, Washington, D. C.

Various combinations of penicillin, streptomycin, aureomycin, chloramphenicol, bacitracin, polymyxin, sulfanilamide, sulfadiazine, sulfathiazole and sulfamerazine were tested in vitro for possible synergistic action, using *Streptococcus hemolyticus* C 203 Mv as a test organism. In these experiments organisms were injected with and without mucin. When mucin was used the virulence of the streptococci was markedly increased; relatively larger doses of the antibacterial agents were required and changes in the ratios of combinations showing a synergistic effect resulted. The results obtained in experi-

mental infection emphasize the difficulty of translating experimental observations into terms of clinical effectiveness.

Alteration and Inhibition of Sea-Urchin Egg Division by Antibiotics. IVOR CORNMAN. Sloan-Kettering Institute for Cancer Research, New York, N. Y.

As a part of a cancer chemotherapy screening program, sea-urchin eggs are being used to detect substances which inhibit cell division and in the study of their effects on mitosis. The eggs of *Arbacia* and *Lytechinus* are exposed ten minutes after fertilization. Normally, cleavage follows at 50-60 minutes after fertilization at 23°-26° C. Divided eggs are counted at intervals to determine inhibition or retardation of cleavage, and such abnormalities as are visible in the living egg are recorded.

Crude penicillin has received special attention because of its ability selectively to kill tumor cells and because Burk has found it to contain a potent metabolic inhibitor. Older pharmaceutical grades of penicillin retarded cleavage at about 300 mg/L. A series of five penicillins supplied by Burk proved to have relative potencies of 1:2:200 (three having the middle rating) compared with respiratory inhibition ratings of 1:10:300. Burk's partially purified *Penicillium* was effective at 5 mg/L, while purified penicillin required 1 g/L to retard cleavage.

A series of filtrates from *Aspergillus* cultured under a variety of conditions were nearly all effective in retarding cleavage. Gliotoxin displayed a distinctly different pattern of action, quickly destroying the eggs when used at concentrations sufficient to delay cleavage (2 mg/L). Percentages of eggs completing second cleavage were: 100 per cent, 30 per cent, and 0 per cent at 1, 2, and 4 mg/L.

Clavacin is another of the more active purified antibiotics, inhibiting all cleavage at 5 mg/L. It was, therefore, more active than its component parts tested separately: the pyrone ring and the five-membered lactone ring.

Search for New Antibiotics

The Isolation and Purification of Neomycin. E. AUGUSTUS SWART, SELMAN A. WAHSMAN, and DOVVIS HUTCHISON. New Jersey Agricultural Experiment Station, Department of Microbiology, Rutgers University, New Brunswick, N. J.

Neomycin has been isolated from culture filtrates of *Streptomyces* 3535 by the following sequence of steps: acidification to pH 2.0-2.5, clarification with activated charcoal, neutralization, adsorption on decal, elution with 10 per cent ammonium chloride, adsorption on activated charcoal from pooled ammonium chloride eluates at pH 7.0, elution by 0.05 N hydrochloric acid in 50 per cent methanol, neutralization by passage through an amberlite IR-4B column or by addition of aqueous sodium hydroxide, concentration "in vacuo" at 35-35° C. to 0.01-0.1 of original volume, picking up residue in methanol and precipitating with acetone, or picking up residue in water and lyophilizing. The concentration of neomycin

chloride showed an average potency of 100 units/mg, some solids ranging as high as 225 u/mg.

Chromatography on columns of Darco G-60 or alumina, using methanol as solvent and eluant, has yielded more highly potent concentrates. Precipitation with picric acid, followed by direct conversion to the hydrochloride, has also given more potent solids.

Another antibiotic, having the same antibacterial spectrum as neomycin but having antifungal activity as well, has been isolated from the culture filtrate. Most of this material was removed by the preliminary acidification of the broth and by treatment with Norit H15, leaving neomycin in the filtrate. Norit A, Amberlite IR-100-H, and decalco adsorbed neomycin from culture filtrate, leaving the second agent in the filtrate.

Neomycin is soluble in water, slightly soluble in methanol, and insoluble in other organic solvents. It is stable at pH 2.1 for one hour at 100° C, four hours at 25° C, and five days at 5° C. A negative Sakaguchi test indicates the absence of mono-substituted guanidine groups. The maximum in the distribution curve occurs at tube 21 when neomycin is distributed between pentasol and borate buffer at pH 7.6, using stearic acid as a carrier, in the 24 plate Craig Counter-current Distribution Machine. Streptomycin and streptothricin show respective peaks, in the same system, at tubes 9 and 8.

Borrelidin, a New Antibiotic with High Anti-Borrelia Activity and Penicillin Enhancement Properties, Produced by a Streptomyces Species. J. BERGER and M. W. GOLDBERG. Research Laboratories of Hoffmann-La Roche, Inc., Nutley, N. J.

An antibiotic with unusual specificity and high activity has been found to be produced by several actinomycetes. It is highly active *in vitro* against *Sarcina lutea* and certain micrococci but relatively inactive against other common test bacteria such as *Staphylococcus aureus*, *Escherichia coli*, and *Bacillus subtilis*. The growth of a protozoan, *Tetrahymena gelcii*, is inhibited at a dilution of 1:200,000. As little as 0.0001 mg. per ml. can be detected by the cylinder plate technique when *S. lutea* is used as test organism. The substance has been isolated in crystalline form (L. M. Jampolsky and M. W. Goldberg) and was named "Borrelidin" because of its outstanding activity *in vitro* against *Borrelia* species (R. J. Schmitzer *et al.*).

The culture producing the best yield of borrelidin is a new *Streptomyces* species. It grows readily on complex organic media, but only sparingly on synthetic liquid media. Under usual methods of handling, the culture yields strains which vary widely in appearance and antibiotic production. Borrelidin is produced by the *Streptomyces* in a variety of liquid media, in stationary shallow layers or in aerated submerged culture. Particularly suitable are media containing soybean meal, glucose, and phosphate.

Small amounts of borrelidin-like substances have been found in sources of penicillin enhancement factors, such as inactivated impure penicillin, clarase enzyme prepara-

tions and even in corn steep liquor. In spite of the fact that pure borrelidin does enhance penicillin activity *in vivo* (E. Grunberg *et al.*), no claim can be made for its identity with any of the postulated penicillin enhancement factors since certain differences have also been observed.

Isolation of Crystalline Borrelidin from Streptomyces Broth and of Borrelidin-Like Concentrates from Crude Penicillin. L. M. JAMPOLSKY and M. W. GOLDBERG. Research Laboratories of Hoffmann-La Roche, Inc., Nutley, N. J.

A new antibiotic, borrelidin, has been isolated in crystalline form from the culture medium of a new *Streptomyces* species. The antibiotic exhibits an unusual degree of specificity, being highly active only against *Sarcina lutea in vitro* and against several strains of *Borrelia in vivo*. Concentrates exhibiting some of the biological properties of borrelidin were also obtained from crude penicillin and other sources reported to contain penicillin enhancement factors. Borrelidin itself was found to enhance the activity of penicillin in certain experimental infections of mice (E. Grunberg *et al.*).

Borrelidin can be isolated from the culture solution by extraction with butyl acetate. The residue obtained by evaporation of the extract can be purified by treatment with bentonite clay in various solvents and finally, by extraction from ether with alkali. Concentration of a benzene extract of the acidified alkali solution yields crystalline borrelidin. Recrystallization from benzene gives pure borrelidin, m.p. 145-146°, $[\alpha]_D^{27} = -28^\circ$ in ethanol.

Borrelidin is an acid. A crystalline methyl ester (m.p. 153-154°) and a crystalline p-nitrobenzyl ester (m.p. 161°) have been obtained. The methyl ester yields a crystalline diacetyl- (m.p. 190°) and a crystalline di-p-nitrobenzoyl-derivative (m.p. 156-157°). The micro-analytical data so far obtained indicate an empirical formula of $C_{23}H_{44}O_6N$ for borrelidin. The ultra-violet absorption spectrum in isopropanol shows a maximum at 256 μ ($E_{1\%}^{1\text{cm}} = 550$), indicating a site of conjugated unsaturation in its molecule.

Enhancement of Penicillin Activity by Borrelidin. E. GRUNBERG, D. ELDRIDGE, and G. SOO-HOO. Research Laboratories of Hoffmann-La Roche, Inc., Nutley, N. J.

The new antibiotic, borrelidin, the principal chemical and biological properties of which have been described in the preceding abstracts, did not show any demonstrable chemotherapeutic activity *in vivo* if tested in experimental infections with β -hemolytic streptococci, pneumococci type 1 and 2, *Klebsiella pneumoniae*, *Salmonella schottmuelleri*, *Eberthella typhosa*, *Mycobacterium tuberculosis*, strain H37Rv, and *Cryptococcus hominis*. This substance, however, possessed some growth inhibiting effect *in vitro* against the organisms enumerated above.

Attempts were made to show that borrelidin possesses properties of enhancement of crystalline Penicillin G similar to those described for unknown factors obtained by inactivation of impure penicillin (Hobby *et al.*, Dunham

et al., Miller *et al.*, Cole, Burk *et al.*, and Welch *et al.*). It could indeed be demonstrated that the addition of very small amounts of borrelidin increased the effect of crystalline Penicillin G in experimental infections with group A, type 3 hemolytic streptococci. The findings may be summarized by the comparison of the CD50 of Penicillin G in the presence and absence of borrelidin.

Single treatment	CD50 of Penicillin G
Cryst. Penicillin G alone	0.56 mg/kg (935 units/kg) subcut.
Cryst. Penicillin G + borrelidin 0.2-1.7 μ g/kg	0.25 mg/kg (417 units/kg) subcut.
Cryst. Penicillin G alone	1.16 mg/kg (1,937 units/kg) per os
Cryst. Penicillin G + borrelidin 3.0 μ g/kg	0.71 mg/kg (1,185 units/kg) per os

There was also found a marked trend to enhancement of Penicillin G by borrelidin in experimental rabbit syphilis, in the protection of mice against meningococcal endotoxin, and in the growth inhibition of *Trichomonas vaginalis*. In addition borrelidin inhibited the respiration of staphylococci as tested by the methylene blue method.

We were, however, not able to demonstrate with borrelidin the enhancement of Penicillin G in infections with *E. typhosa* as described by Welch and with type 1 pneumococci as described by Hobby. The enhancement of Penicillin G in infections with *Salmonella schottmuelleri* was also not observed.

No definite statement can be made at the present time regarding the identity of borrelidin and any of the enhancement factors described.

The Anti-borrelia Effect of Borrelidin. R. J. SCHNITZER, M. BUCK, and A. C. FARR. Research Laboratories of Hoffmann-La Roche, Inc., Nutley, N. J.

During the routine screening in experimental infections of mice it was found that borrelidin, a new antibiotic found and isolated in crystalline form by M. W. Goldberg and his associates, J. Berger and L. M. Jampolsky (see the abstracts of these authors), exerted a striking effect on borrelia infections. This is illustrated by the following table:

Animal	LD50	CD50: μ g/kg		
		Borrelia tick	B. Noryi	B. Obermerieri
Mice	μ g/kg 74.7	0.6	2.0	1.7
Rats	1.78	—	—	0.9

Borrelidin-like substances in concentrates from impure penicillin, clarase and corn steep had a similar activity.

Borrelidin was also effective toward a partially penicillin resistant strain of *B. Noryi*. It was comparatively easy to produce a borrelidin fast strain of *B. Obermerieri* which still responded to As-compounds, Au-compounds, penicillin and aureomycin. This indicates that borrelidin represents a type of anti-borrelia agent different from those mentioned before.

No effect of borrelidin was seen in experimental rabbit syphilis and in trypanosomal infections. The compound exerted, however, a growth inhibiting effect on *Trichomonas vaginalis* *in vitro* in concentrations of 0.004-0.006 mg/ml.

Borrelidin is a substance of considerable toxicity. The LD50 for mice was found to be 74.7 mg/kg and 39.0 mg/kg if given by the subcutaneous and intravenous route respectively. Other animals, *e.g.*, rats and rabbits, were considerably more sensitive to this material. Moreover, the new antibiotic is irritant to the tissues of animals and sometimes to the skin of humans.

Candidulin: an Antibiotic from Aspergillus candidus. P. G. STANLEY and N. H. ANANENKO. Chemotherapy Division, Stamford Research Laboratories, American Cyanamid Company, Stamford, Conn.

A substance has been recovered from the fermentation liquor of a strain of *Aspergillus candidus* which has marked activity against acid-fast bacteria. The properties of the active principle distinguish it from known antibiotics. The name "candidulin" is proposed for it.

Moderately active fermentation liquor may be obtained in stationary culture on a neutral substrate consisting of glucose, sodium nitrate and potassium phosphate. The active principle may be removed from the metabolic liquor with chloroform and crystallized from n-hexane. The yield of purified material is about 5 mg. per liter. The substance is a colorless, neutral, non-aromatic compound, m.p. 88-89°, $[\alpha]_D^{25} = +15^\circ$ (chloroform). Elemental analysis is consistent with an empirical formula of $C_{12}H_{12}NO_4$. Treatment with bromine in carbon tetrachloride afforded a biologically inactive crystalline product containing bromine, m.p. 143-147° (dec.).

In broth dilution tests, the antibiotic exhibits moderate activity against some Gram-positive and Gram-negative bacteria. It is particularly effective against the mycobacteria, inhibiting the growth of five strains, representing pathogenic and saprophytic species, in concentrations of approximately 1 μ g. per ml. The substance, however, failed to influence the course of experimental mouse tuberculosis when administered subcutaneously in daily doses of 25 to 200 mg. per kg.

Inhibitory Action of Filtrates from Fungous Cultures on Three Plant Viruses. W. C. PRICE, B. M. GURTA, and SYLVIA WOLCZEZ. Department of Biological Sciences, University of Pittsburgh, Pittsburgh, Pa.

Filtrates from three-weeks-old cultures of about 40 species of fungi grown on lacto-beef-cornmeal-dextrose broth were tested for ability to inhibit infection with Southern bean mosaic, tobacco mosaic, and tobacco ring-spot viruses. Filtrates from *Trichothetium reesei*, *Neurospora sitophila*, and *N. crassa* were found to inhibit infection with all three viruses. The inhibitory action took place immediately whether the filtrate was mixed with the virus or applied to the host before or up to 30 minutes after infection.

¹ Aided by a grant from the National Foundation for Infantile Paralysis.

ter inoculation. Virus preparations rendered inactive by addition of filtrate regained their activity when diluted. These results can be interpreted to mean that the filtrates either render the host insusceptible to the virus or enter into a reversible combination with the virus. Evidence favoring the former interpretation was obtained by study of the reduction in infectivity induced by addition of varying quantities of antiviral agent to a constant dilution of virus. The reduction in infectivity, as expressed in probits (or normal equivalent deviations), was found to be a linear function of the logarithm of dilution.

Marine Organisms as a Source of Physiologically Active Substances. IVOR CORNMAN. Sloan-Kettering Institute for Cancer Research, New York, N. Y.

Every phylum of the animal kingdom has members which possess poisonous tissues or toxic secretions. Representative species have been tested according to the method outlined in an accompanying abstract.

The protozoan, *Gymnodinium brevis*, believed responsible for the "red tide" which periodically kills millions of fish and shellfish, produces a poison which checks the division of sea-urchin eggs.

Sponges crushed in sea water vary in their inhibitory potency. Of ten species tested, two exerted a slight effect only after several hours when diluted 1:100. Four species retarded the first cleavage at 1:100 and showed a delayed effect at 1:1,000. One allowed only 7 per cent of the eggs to divide when the sponge macerate was diluted 1:1,000 and retarded cleavage at 1:10,000. Another produced no measurable effect for several hours and then killed the larvae at all doses tested (1:100, 1:1,000, 1:10,000). These differences in dose-effect relationships reveal a qualitative as well as a quantitative difference in the active agents. The most toxic sponge species permitted only a few eggs to divide and visibly damaged the cytoplasm in a half hour when diluted 1:10,000. Even at 1:100,000 it killed the embryos but required several hours to take effect.

The spines of *Centreechinus* are poisonous enough to produce a painful swelling when they puncture the skin, and many species of fish cannot survive in tanks containing these sea urchins. A brei prepared from the spines proved to be only a weak inhibitor of cleavage.

Numerous mollusks release an ink when disturbed. A large sea slug, *Tethys*, ejects a raspberry-odored red fluid which blocks egg development at 1:1,000. *Thais patula* exudes a white garlic-odored fluid which turns blue. This blue solution retards cleavage when diluted 1:10 and is without influence at 1:100. Mantle fluid from *Thais deltoidea*, which has no ink, is harmless at 1:10.

Aureomycin and Chloramphenicol

The Assay of Aureomycin by Instrumental Methods. HOWARD STONE KILGAY and LEON GOLDMAN. Lederle Laboratories Division, American Cyanamid Co., Pearl River, N. Y.

Two methods based on a standard solution of aureomycin HCl are outlined for measuring the potency of aureomycin solutions.

A fluorometric method involves a five-min. boiling of 100–400 μ g. of the antibiotic with an equimolecular mixture of Na_2PO_4 and Na_2HPO_4 . On dilution, the resulting fluorescence is measured on a Pfaltz and Bauer fluorophotometer, using the same filter system as the Vitamin B₁ assay. A blank solution, made up to the same dilution, employs a PO_4 buffer to give a pH = 10, being read immediately without heating. The difference between readings represents the amount of Aureomycin present.

A colorimetric method uses a sample ranging from 100 to 1,400 μ g. This sample is treated with twice its volume of conc. HCl for 10 min. when it is diluted for reading on a Lumetron Colorimeter (Model 402-E) using M440 filter. A blank solution is prepared using the same ingredients but adding the acid to the diluted sample. The galvanometer is set at 100 per cent transmittance with the blank solution after which the "treated solution" is read.

Both methods give a straight line standard curve on linear paper. Both give results comparing favorably with a microbiological assay method.

*Studies on Assay Methods of Aureomycin in Body Fluids.*¹ C. M. WHITLOCK, JR., A. D. HUNT, JR., and S. G. TASHMAN. Children's Hospital of Philadelphia, Department of Pediatrics, University of Pennsylvania, Philadelphia, Pa.

The accuracy of the two basic methods of aureomycin assay which seemed most promising (namely, the serial dilution method of Dornbush and the turbidimetric method of Meads) was assessed by measuring known quantities of aureomycin in the presence of various human body fluids with both methods. Similar data have not been previously reported. For concentrations greater than 0.1 μ g./cc., the serial dilution method was found to be accurate within ± 100 per cent in serum and urine, and to be inaccurate in spinal fluid (errors of 100 per cent or over being common). For similar concentrations, the turbidimetric method was found to be accurate within ± 50 per cent in serum, and ± 100 per cent in urine and spinal fluid.

In the above comparison, the technique used was essentially the same as that of the originators of the methods. When the turbidimetric method was modified by substituting a standard curve containing four points for the single standard used by Meads, the experimental error was reduced to within ± 25 per cent in serum, ± 35 per cent in spinal fluid, and ± 45 per cent in urine. This change also simplifies the method by eliminating most of the mathematical detail work. This laboratory now uses this modified turbidimetric method exclusively for the assay of aureomycin.

¹ These studies were conducted under contract with the Department of the Army, Chemical Corps, Camp Detrick, Md.

Investigation of plate methods of assay was terminated with inconclusive results when it was learned that this type of method measures aureomycin only in concentrations of about 1 $\mu\text{g./cc.}$ or greater.

Using the turbidimetric assay method, it was determined that serum and acid urine specimens can be frozen and assayed in weekly lots without appreciable loss of aureomycin activity. Spinal fluid must be run on the day collected, however, if concentrations of less than 1 $\mu\text{g./cc.}$ are to be accurately measured. When 1 $\mu\text{g./cc.}$ of aureomycin in serum was incubated three hours at 37° C. before assay, there was less than 15 per cent loss of potency. This observation suggests that the degree of destruction of aureomycin under physiological conditions has been over-emphasized.

Aureomycin Studies. I. Effect of Aureomycin on Ten Strains of Virus in the Psittacosis-LGV Group. JOHN C. WAGNER. Biological Department, Chemical Corps, Camp Detrick, Frederick, Md.

A recent report (Cox *et al.*) on the efficacy of aureomycin on the 6BC strain of psittacosis virus made it appear desirable to obtain additional data on the action of this antibiotic on other virus strains within the psittacine group. This report presents the results of such a study in both eggs and mice on ten strains of virus in the psittacosis-lymphogranuloma venereum group.

Drug effect was evaluated in eggs by comparing the LD₅₀ values of each virus strain titrated in untreated as compared to aureomycin treated embryos. In animal studies mice were inoculated intracerebrally with each virus strain and treated, beginning 48 hours later, by five daily subcutaneous inoculations of varying amounts of aureomycin.

In the egg experiments all the virus strains were extremely susceptible to aureomycin. In high dilution the virus was almost completely masked by the presence of drug as manifested by survival of eggs and low titer of virus on subinoculation. As the virus concentration increased, the masking effect could be demonstrated only by survival of treated embryos, but not by titer of recoverable virus within these embryos. All five pathogenic strains (Borg, S-F, Gleason, 6BC, P207) tested in mice were susceptible to the drug. Injections of 0.5 mg. or 0.1 mg. of aureomycin lengthened significantly the life span of treated groups of animals as compared to untreated controls. Living virus was recovered after 21 days from the brains of all treated groups of surviving mice.

The Action of Aureomycin on the Virus of Atypical Pneumonia in Chick Embryos and Cotton Rats. MONROE D. EATON. Department of Bacteriology and Immunology, Harvard Medical School, Boston, Mass.

The virus isolated from patients with atypical pneumonia as described in previous publications¹ is unrelated

antigenically to Q fever or to agents of the psittacosis group, both of which are inhibited by aureomycin. Chick embryos inoculated by the amniotic route with the atypical pneumonia virus received two doses of aureomycin of 1 mg. each into the yolk sac two and 48 hours after the virus was given. The lungs, trachea and amniotic membrane of the treated embryos were pooled, made up in 20 per cent suspension, and inoculated intranasally into cotton rats to test for the presence of virus. Control embryos receiving virus and saline were similarly tested. The cotton rats were sacrificed ten days after inoculation. Of the 27 cotton rats receiving material from the treated eggs, one developed pulmonary lesions, while 20 of the 26 animals receiving control material developed areas of consolidation. When a single dose of 1 mg. of aureomycin was given two hours after the virus, treated eggs produced lesions in eight of 28 cotton rats, and controls in 17 of the 26 cotton rats, a less significant difference probably due to early decomposition of aureomycin in the chick embryo.

Direct treatment of cotton rats infected intranasally with chick embryo material and given daily intraperitoneal doses of 1 to 2 mg. of aureomycin starting 24 hours after inoculation of the virus also resulted in significant therapeutic effects on the pulmonary lesions. The incidence of pulmonary lesions in animals treated in this manner was as follows: 0/9 in those receiving 2 mg. daily for ten days, 1/22 in those receiving 1 mg., and 27/46 in the controls. Preliminary results indicate that the minimal therapeutic dose in cotton rats may be close to 0.5 mg. daily or approximately 10 mg./kg. body weight.

Clinical Evaluation of Aureomycin and Chloramphenicol in Pneumonia in Infants and Children. BENNETT OLSHAKER, SIDNEY ROSS, ADRIAN RECINOS, and ELLSWORTH TWIBLE. Children's Hospital, Washington, D. C.

Aureomycin

Forty cases of pneumonia in infants and children have been treated with aureomycin during the past three months at Children's Hospital. Of these, 32 were pyogenic pneumonias including pneumococcus, streptococcus and staphylococcus. The other eight cases appeared to satisfy the diagnostic criteria of atypical pneumonia.

In the pyogenic group the response both clinically and bacteriologically was striking. The temperature came down precipitously within 12 to 36 hours in almost every case and concomitantly a marked clinical improvement ensued. Roentgenologically, the resolution of the pneumonic process was rapid in the majority of cases; however, in about 20 per cent of the cases there was a lag in the resolution of the area of consolidation by x-ray approximating five to eight days. The drug was well tolerated orally with the exception of the occasional occurrence of nausea, vomiting and diarrhea. Ten of the cases in the infant age group received the drug intramuscularly and showed a prompt response in the majority of instances. However, it was our impression that the intramuscular mode of administration was less satisfactory therapeutically than the oral method of administration.

¹Eaton, M. D., McEldreigh, G., and Van Herick, W. J. Exp. Med., 1945, 82, 317-329. Am. J. Hygiene, 1947, 45, 82.

In the eight cases of atypical pneumonia the therapeutic response was similarly gratifying and seemed to follow the favorable course which Schoenbach and Bryer and Finland and his associates have described in their series of virus pneumonias in adults.

Chloramphenicol

Twenty-seven consecutive cases of bacterial pneumonia in infants and children were treated with chloramphenicol. The age range varied from five months to eight years. In 25 of the 27 cases, there was a prompt defervescence of temperature within 12 to 36 hours after initiation of the drug accompanied by marked clinical improvement. The white blood count dropped sharply and the areas of consolidation on x-ray showed resolution within three to six days. The results thus far would indicate that chloramphenicol has definite therapeutic value in bacterial pneumonia.

Some Observations on the Absorption and Excretion of Aureomycin and Chloramphenicol. SIDNEY ROSS, HAROLD BISCHOFF, WARREN PREISSER, and WILLIAM ORR. Children's Hospital, Washington, D. C.

A. Chloramphenicol

- (1) Chloramphenicol was observed to pass through the placental barrier and was present in cord blood in a concentration of 50 to 75 per cent of that observed in the maternal blood.
- (2) Chloramphenicol readily passed the blood-brain barrier and appeared in the spinal fluid in concentrations ranging from 30 to 50 per cent of that noted in the blood stream after oral administration.
- (3) No enhancement in chloramphenicol blood levels was noted after concomitant oral administration of caronamide.
- (4) Chloramphenicol was readily absorbed after rectal administration of 125 to 250 mgms. in infants and appeared in the blood in therapeutic concentrations.

B. Aureomycin

- (1) Aureomycin was found in the pleural and peritoneal fluids of a nephrotic child after oral administration of 250 mgms. every four hours. The concentration of aureomycin in these fluids was approximately one-eighth of that noted in the blood.
- (2) Aureomycin was absorbed into the blood stream after rectal administration of 250 mgms. in children.

Observations on Tuberculous Meningitis Treated with Oral Aureomycin.^{1,2} GEORGE T. HARRELL, MANSON MEADS,³ ROBERT B. LAWSON, and THOMAS N. LIDE.

¹ This study was supported (in part) by a research grant from the Division of Research Grants and Fellowships of the National Institutes of Health, U. S. Public Health Service.

² The aureomycin used in this study was furnished by Lederle Laboratories.

³ Markle Scholar in Medicine.

Departments of Internal Medicine, Pediatrics and Pathology, Bowman Gray School of Medicine of Wake Forest College and the North Carolina Baptist Hospital, Winston-Salem, N. C.

In vitro observations showed that tubercle bacilli were susceptible to aureomycin. This antibiotic was found to penetrate into the spinal fluid after oral administration. These facts suggested possible application of the drug to therapy in tuberculous meningitis.

A four-year-old boy weighing 14 kilo. had fulminating symptoms of meningitis for three days. Acid-fast rods were found in large numbers on direct smear of spinal fluid. A critical study was done on the effect of very large doses of aureomycin (300-500 mg. per kilo., 4-8 grams daily) given only orally over 21 days. Almost daily blood and spinal fluid levels of aureomycin were obtained. Blood levels (2-15 μ g./cc.) varied more widely than spinal fluid levels (1-3 μ g./cc.) and both varied reciprocally with the number of stools (one to eight per day). Organisms disappeared on smear and the spinal fluid sugar rose from 10 to 40 mg.%. Clinical improvement was steady for over two weeks; a sudden worsening in the third week terminated fatally.

At autopsy caseous lesions were found in lymph nodes and spleen with no evidence of healing. The drug apparently did not reach intracellular organisms deep in tubercles. Serial cultures were planted directly and the susceptibility of the organisms to aureomycin was determined after recovery from guinea pigs inoculated with spinal fluid and tissue.

No toxic effects were noted pathologically from this huge dose—the largest yet recorded—administered for a relatively long time. The negative spinal fluid cultures without intrathecal therapy may justify further study of aureomycin in combination with other forms of therapy in this disease.

A Comparative Study on the Effects of Aureomycin and Penicillin on the Pharyngeal Flora of Normal Human Beings.^{1,2} MANSON MEADS,³ WALLACE P. ROWE, and NANCY M. HASLAM. Department of Internal Medicine, Bowman Gray School of Medicine, Wake Forest College, Winston-Salem, N. C.

The effects of aureomycin and penicillin on the aerobic bacterial flora of the pharynx were compared in normal human subjects. Repeated semiquantitative throat cultures were taken from the same individual before, during, and after the successive oral administration of the two antibiotics in different doses. By utilizing each subject as his own control, host factors that may influence chemo-

¹ This investigation was supported (in part) by a research grant from the Bacteriology Study Section, Division of Research Grants and Fellowships of the National Institutes of Health, U. S. Public Health Service.

² The aureomycin and penicillin used in this study were furnished by Lederle Laboratories Division, American Cyanamid Company, Pearl River, N. Y., through the courtesy of Dr. Stanton M. Hardy.

³ Markle Scholar in Medicine.

therapeutic response were minimized. Repeated tests were made of the *in vitro* susceptibility of the bacteria recovered throughout the period of observation. The *alpha hemolytic streptococci* proved to be a good index for the comparison of certain aspects of the antibacterial activity of the two drugs because of (1) their susceptibility to aureomycin and penicillin, (2) their constant appearance in normal pharyngeal cultures, and (3) their consistent reappearance after effective therapy had been stopped.

With the exception of the genus *Hemophilus*, aureomycin and penicillin demonstrated a similar spectrum of antibacterial activity. By weight, penicillin was approximately five times more effective than aureomycin against *alpha streptococci* in the human pharynx; penicillin was 12 times more active against these organisms *in vitro*. In most instances, a drug-specific decrease in the mean *in vitro* susceptibility of *alpha streptococci* and *Neisseria flava* paralleled a failure to clear these organisms from the pharynx. The mean increase in resistance to penicillin was maintained throughout a three-week period after this drug had been discontinued. The degree of aureomycin-fastness that followed treatment with this agent slowly decreased *in vivo*, although repeated transfer of resistant organisms in media free of antibiotic failed to effect their degree of susceptibility. The apparently stable property, fastness to penicillin, was used as a label to study the dynamics of aureomycin-fastness in pharyngeal bacteria.

This method of antibiotic comparison may serve as a valuable tool to supplement laboratory studies on a new chemotherapeutic agent before it is used in clinical disease.

Isolation and Chemistry of Chloramphenicol (Chloromycetin¹). QUENTIN R. BARTZ. Research Laboratories, Parke, Davis and Company, Detroit, Mich.

The activity of chloramphenicol, a new crystalline antibiotic obtained from filtrates of submerged aerated cultures of *Streptomyces venezuelae*, was followed by means of a turbidimetric method employing *Shigella paradysenteriae* (Sonne) as the test organism. It was stable at 25° in culture filtrates over the pH range of 0.40–9.56 for 24 hours but was rapidly destroyed at pH 10.82. The distribution ratio at 25° of chloramphenicol between organic solvent and either acidified or weakly alkaline aqueous solution was found to be three or more for cyclohexanone, butanol-1, ethyl acetate, methyl isobutyl ketone, isopropyl acetate, amyl acetate, methyl amyl acetate, nitrobenzene, nitromethane and diethyl ether; approximately one for ethylene dichloride, and less than one for chloroform, carbon tetrachloride, trichloroethylene, benzene, dichloroethyl ether, and petroleum ether. Chloramphenicol is readily absorbed by Nuchar C190N from aqueous solution at either an acid or neutral pH.

Two general procedures for the isolation of chloramphenicol in crystalline form from crude culture filtrates involve (1) extraction with water-immiscible organic

solvents or (2) adsorption on carbon and elution with organic solvents.

Chloramphenicol is an optically active, nonionic chlorine-containing amide, melting at 149.7–150.7°, the molecular formula of which is $C_{12}H_{12}ClN_2O_6$. The assigned structure has been confirmed by an unequivocal synthesis (Controulis, Rebstock and Crooks).

Chloramphenicol (Chloromycetin¹) Assay and Susceptibility Test Methods. D. A. JOSLYN, J. EHRLICH, and J. L. SCHWAB.² Research Laboratories, Parke, Davis & Company, Detroit, Mich.

The chloramphenicol content of aqueous solutions and body fluids has been determined by three microbiological methods. **Turbidimetric Method:** Samples are diluted to an estimated concentration of 0.2 microgram chloramphenicol per milliliter in brain heart infusion (Difco) containing a standardized inoculum of *Shigella sonnei*; after *ca.* four hours' incubation at 37° C., potency is calculated by comparing turbidity of the sample tubes with that of control tubes containing 0.1 to 0.5 µg. of a standard chloramphenicol per milliliter. **Overnight Broth Method:** Samples are diluted serially as required in brain heart infusion containing a standardized inoculum of *S. sonnei*; after *ca.* 18 hours' incubation at 37° C., the concentration of chloramphenicol in the sample is estimated by comparing the end point (complete inhibition) of the sample with that of a standard. **Agar Diffusion Method:** Uniform volumes of appropriately diluted samples and standard are added to one-half inch diameter filter paper disks placed on agar plates seeded with *Bacillus subtilis* or other susceptible test organism; potency is estimated by comparing the resulting inhibition zone diameters with aid of a standard curve.

The susceptibility of cultures, particularly those isolated from candidates for chloramphenicol therapy, has been tested by two microbiological methods. **Agar Dilution Method:** Tryptose agar dilutions of chloramphenicol are streaked with clinical material; after suitable incubation, presence or absence of growth in the several plates indicates the degree of susceptibility. **Broth Dilution Method:** Tryptose broth dilutions of chloramphenicol are inoculated with a standardized suspension of the cultures on test; after suitable incubation, the degree of susceptibility is indicated by complete inhibition of growth.

A Colorimetric Method for the Determination of Chloramphenicol (Chloromycetin¹): Application to Biochemical Studies. ANTHONY J. GLAZKO, WESLEY A. DILL, and LORETTA M. WOLF. Research Laboratories of Parke, Davis and Company, Detroit, Mich.

The colorimetric method used for the determination of Chloromycetin and related aromatic nitro compounds is based on reduction with metallic zinc or titanium chloride.

¹ The name Chloromycetin has been adopted by Parke, Davis & Company as a trademark for this antibiotic.

² Chloromycetin is the Parke, Davis and Company trade name for chloramphenicol.

³ With technical assistance of M. C. Galbraith, D. Fox, M. L. Davitt, M. E. Shedian and F. E. Grest.

followed by diazotization and coupling of the resulting aryl amine with the Bratton-Marshall reagent. The active antibiotic can be separated from its metabolic products by extraction with ethyl acetate and determined separately. The titanous procedure has also been used for the development of color on paper strips after chromatographic separation of various Chloromycetin derivatives.

Blood level studies on man and lower animals indicate rapid absorption and excretion of this antibiotic. Human subjects given Chloromycetin by mouth were found to excrete aromatic nitro compounds which accounted for more than 90 per cent of the administered dose in 24-hour urine specimens. Less than 10 per cent of this was found to be active Chloromycetin which was isolated from urine and identified.

The inactive metabolic products were chromatographed on paper strips, and one component was shown to have the same R_f value as a known hydrolysis product of Chloromycetin. The other inactive derivative, representing the major excretory product, was isolated by countercurrent extraction and tentatively identified as the mono-glucuronide. This metabolic product was readily hydrolyzed with β -glucuronidase, yielding active Chloromycetin.

No increase was observed in the urinary excretion of aryl amines in man following the administration of Chloromycetin, but lower animals such as the mouse, rat, and guinea pig excreted aryl amines in addition to inactive nitro compounds. *In vitro* studies with tissues of the rat and guinea pig demonstrated the presence of enzyme systems which converted Chloromycetin to inactive nitro compounds and also reduced the nitro groups to produce aryl amines.

Chloromycetin in Salmonellosis. S. ROSS, F. G. BURKE, E. C. RICE, and J. A. WASHINGTON. Children's Hospital, Washington, D. C.

Five cases of salmonellosis have been treated or are being treated with Chloromycetin at Children's Hospital. Two of these five cases are carriers who have failed to respond to streptomycin, aureomycin, or aerosporin during the past four months. The efficacy of Chloromycetin in these cases is too early to evaluate. The stool cultures are now negative for the first time in four months; however, insufficient time has elapsed for an adequate follow-up. The dose used was 125 mgm. every four hours orally for 10 to 14 days.

A third case had a positive blood culture for salmonella on admission. After administration of the drug, subsequent blood cultures became sterile and a positive stool culture was not obtained at any time. The child made an uneventful recovery. A fourth case currently under treatment has shown a persistence of positive stool cultures during the first four days after initiation of the drug.

The fifth case was a critically ill child with a positive blood culture. Chloromycetin was started shortly after the positive blood culture was obtained; however, the child died within 12 hours. The duration of therapy was too short to permit any evaluation of the efficacy of the drug in this case.

It would seem thus far that Chloromycetin might be more promising in salmonellosis than any antibiotic we have used; however, a larger number of cases and a longer follow-up would be mandatory before any categorical statement could be made.

Chloromycetin¹ in Therapy of Bacillary Urinary Infection. GEORGE E. CHITTENDEN, ELWOOD A. SHARP, A. J. GLAZKO, and A. S. SCHLINGMAN. Research Laboratories, Parke, Davis and Company, Detroit, Mich.

When the clinical investigation of the antibiotic effect of Chloromycetin in bacillary urinary tract infections was begun, only fragmentary data on blood levels, urine concentrations and excretion rates were available. As a result, numerous dosage patterns were studied. Some patients were given large (3.0 Gm.) single doses and were followed by frequent urinary cultures and blood levels. Others were given 2.0 Gm. single doses followed by 0.5 to 1.0 Gm. at four to eight hour intervals.

As a result of a study of approximately 50 patients, the following facts have been determined:

- (1) Chloromycetin appears to be a safe drug, especially when given orally in a wide range of dosage patterns. Thus, in mild to moderate bacillary infections, 0.5 Gm. every six to eight hours around the clock will maintain a satisfactory therapeutic blood level. In severe cases, a large initial dose (1.0 to 3.0 Gm.) followed by maintenance doses of 0.5 Gm. every six to eight hours will be adequate.
- (2) Therapy may be continued for a long period of time with no adverse pathological reactions. In one case, approximately 54.0 Gm. were given continuously without toxic or allergic reactions.
- (3) Since our studies have indicated the frequent presence of a multiplicity of organisms (Gram-positive and Gram-negative), treatment of urinary infections with sulfadiazine or penicillin in addition to Chloromycetin may be indicated.

Aureomycin and Chloramphenicol: Use in Typhus, Typhoid and Brucellosis. VERNON KNIGHT, WALSH McDERMOTT, and FRANCISCO RUIZ-SANCHEZ. Department of Medicine of the New York Hospital-Cornell University Medical College, New York, N. Y., and the Institute for the Experimental Study of Infections of the University of Guadalajara, Mexico.

Twenty-eight patients with typhus fever, presumably of murine variety, have been treated with aureomycin. The majority of a group of 23, treated by oral administration, received 100 to 200 mg. per Kg. per day for periods of one to two days with dramatic improvement and prompt clinical remission.

Other patients were treated with lower oral doses and by the intravenous route. These studies indicated that 50 mg. per Kg. per day orally for 36 to 48 hours was the lowest limit of effective dosage and that a dose of 25 mg.

¹ Trade-Mark Parke, Davis and Company for chloramphenicol.

per Kg. per day for 36 hours was sub-effective. Sub-effective and effective doses of 400 mg. and 1,000 mg. intravenously respectively in a 48 hour period of time were observed.

It was concluded that aureomycin constitutes highly effective therapy for typhus fever and that an approximate oral-intravenous ratio of effectiveness of one to five exists in this disease.

Twenty-three patients clinically ill with brucellosis, of whom nine had positive blood cultures for *B. melitensis*, were treated with aureomycin and chloramphenicol. The treated groups were almost equally divided and received similar doses of these drugs for periods averaging about eight days in doses ranging from 50 to 100 mg. per Kg. per day. Prompt clinical remission occurred in both groups after therapy. No significant differences were observed in the degree and duration of fever after therapy, although the clinical impression was gained that slightly more chloramphenicol than aureomycin was necessary to produce comparable results in the treatment of this infection. Frequent relapses make necessary further study of dosage regimens and evaluation of therapy in terms of permanent remission.

Forty-six patients with typhoid fever, of whom 35 were bacteremic, were treated with chloramphenicol or aureomycin. Dosages of aureomycin ranged from 50 to 500 mg. per Kg. per day for approximate eight day intervals. Chloramphenicol was given in most cases in doses of 100 mg. per Kg. per day for a similar period of time.

Clinical observations revealed that chloramphenicol was far superior to aureomycin in the treatment of typhoid fever, and this was in conformity with the previously reported good results with chloramphenicol. A definite, but slight effect was observable, however, in the aureomycin-treated patients.

Polypeptide Antibiotics

*Chemical Studies of Circulin.*¹ D. H. PETERSON and L. M. REINEKE. Research Laboratories, The Upjohn Company, Kalamazoo, Mich.

Circulin, an antibiotic more active against Gram-negative than Gram-positive organisms, was isolated and purified from the fermentation liquors of a non-hemolytic strain of *B. circulans* by Peterson and Colingsworth, working in cooperation with Murray, Tetrault, Kaufmann and Koffler.

Circulin, like the polymyxins, is a basic polypeptide, but differs from them in amino acid composition and is inactivated by lipase. The active principle was considered pure when repeated carbon chromatography and regeneration from its salts failed to raise the activity or alter its chemical composition. Circulin readily forms salts such as the hydrochloride, picrate, reineckate and helianthate. The antibiotic is insoluble in the water immiscible sol-

vents but is very soluble in water and less soluble in the lower alcohols. Circulin gives a negative ninhydrin-carbon dioxide reaction. Nevertheless, it contains free amino groups as exhibited by the Van Slyke and formalin reactions as well as by its reaction with 2,4-dinitrofluorobenzene.

An optically active isomer of pelargonic acid was isolated from the acid hydrolysate of circulin. Paper strip chromatography, microbiological and isolation studies of this hydrolysate demonstrated the presence of L- α , γ -diaminobutyric acid, L-threonine and D-leucine. From 300 mg. of acid hydrolysate it was possible to separate the amino acids by powdered cellulose partition chromatography in sufficient quantities to identify the constituents by various chemical means.

Paper strip chromatography reveals that the only free basic amino groups of circulin are due to the γ -amino group of α , γ -diaminobutyric acid.

Studies on Circulin. P. A. TETRAULT, H. KOFFLER, O. W. KAUFMANN, and L. Y. QUINN. Laboratories of Bacteriology, Department of Biological Sciences, Purdue University, Lafayette, Ind.

The discovery of an antibiotic which is very active against Gram-negative bacteria and is related to the polymyxins was recently announced by Murray and Tetrault (Proc. Soc. Am. Bact., 1948, 1, 20). This antibiotic is produced by *Bacillus circulans* Q-19 and was therefore named *circulin* in a paper in press which also summarizes information on its assay, isolation, and general properties (Murray, Kaufmann, Tetrault, Koffler, Peterson, and Colingsworth, J. Bact., 57, in press). This antibiotic is not identical with the highly toxic product of *Bacillus krzemieniewski* M-14 which is being studied at the Venereal Disease Research Laboratory and which until recently was also named circulin (McLeod, J. Bact., 1948, 56, 749-754).

Yields which are approximately equivalent to from 50 to 100 mg. of pure circulin sulfate per 100 ml. of medium can be obtained during the submerged growth of *Bacillus circulans* Q-19 in a medium which contains the following: 2 per cent yeast extract, 2 per cent dextrin, 1 per cent $(\text{NH}_4)_2\text{SO}_4$, 0.4 per cent KCl, 0.02 per cent KH_2PO_4 , and 1.6 per cent CaCO_3 . The following chemical changes occurred during a representative fermentation: Bacterial growth proceeded fairly rapidly after inoculation, especially so after 12 hours. Maximum cellular development was reached approximately after 36 hours. Highest circulin yields were obtained 12 hours later. At that time the cells had begun to autolyze. Organic nitrogen compounds appeared to be used in preference to ammonia nitrogen. After 36 hours almost all of the organic nitrogen had been utilized while the concentration of ammonia nitrogen remained relatively unchanged. The utilization of dextrin paralleled bacterial growth. After 26 hours, when a maximum population level had been reached, dextrin was no longer used, although approximately one-fourth of the original amount still remained. While utilizing dextrin the culture produced lactic acid which it then kept on using until it reached maximum growth.

¹ In a recent note to the J. Bact. (In Press) the name Circulin was withdrawn in favor of Mucoidin for an antibiotic described by Charlotte McLeod, J. Bact., 1948, 55, 749.

The pH values reflected these chemical changes. A drop in pH from 7.8 to 6.4 accompanied the production of lactic acid; when the lactic acid was utilized and nitrogen compounds were released, the pH rose from 6.4 to 7.4, and then more gently to 7.8, a pH value reached after 73 hours. Preliminary experiments indicated that circulin protects white mice against infections caused by *Salmonella typhosa*, *Klebsiella pneumoniae*, and *Vibrio cholerae*. The amounts of circulin necessary to accomplish this were from one-seventh to one-fourth as large as the amounts lethal to half of the mice tested.

A Consideration of the Toxicity of Bacitracin Following Systemic Administration. FRANK LAMONT MELENEY and BALBINA JOHNSON. Columbia University, College of Physicians and Surgeons, New York, N. Y.

There is no evidence of toxicity or allergy from the local injection of bacitracin in the treatment of localized surgical infections from the surface application of bacitracin, or from mouth administration of single doses as high as 250,000 units. Nevertheless, evidences of kidney irritation have appeared following the intramuscular injection of doses ranging from 10,000 to 100,000 units administered every four to six hours. These toxic effects have varied strikingly with the different manufactured lots and with different manufacturing methods. This was not fully recognized until June, 1948.

Since July, precautions have been taken to use only those lots which have demonstrated an LD 50 of 300 or more for a 20-gram mouse. In the last eight months, 60 or more cases have been treated successfully with these lots without any evidence of serious kidney damage. This report covers more than 200 cases which clearly reveal not only the variations in toxicity but the safety and effectiveness of lots which have demonstrated, by the FDA tests, an LD 50 of 500 for 20-gram mice. Sixty per cent of these cases have been treated with bacitracin because they failed to respond to other methods of antibacterial therapy and more than half of these have then responded to bacitracin.

Recent experience indicates that there is an increasing number of bacterial infections which do not respond to penicillin and the causative organisms are frequently found to be resistant to penicillin but susceptible to bacitracin. These facts clearly indicate the need for an antibiotic with the attributes of bacitracin.

Bacitracin Therapy of Experimental Staphylococcal Meningitis in the Dog. PAUL TENG and FRANK LAMONT MELENEY. Columbia University, College of Physicians and Surgeons, New York, N. Y.

Early experiments in normal animals demonstrated that bacitracin was held back by the blood-brain barrier and reached the cerebrospinal fluid in only about 10 per cent of the concentration attained in the blood, following intravenous or intramuscular injection. However, this concentration was considerably increased in the presence of local inflammation.

Following the intracisternal injection of 3 cc. of saline containing 10,000 units of bacitracin in normal dogs,

there was some initial stiffness of the neck and pleocytosis; but the animals appeared normal as soon as they recovered from the anesthetic and there was no evidence of injury to the brain or cord.

In a series of 16 dogs in which meningitis was produced by the intracisternal injection of 500 million staphylococci, one-half of the animals were retained as controls while the other half were treated with the intracisternal injection of bacitracin at varying intervals following the inoculation of the organisms. In all of the animals, symptoms of meningitis rapidly developed and in the controls it was invariably fatal in from four and one-half to 37 hours, but the treated animals survived if treatment was begun within three hours following the inoculation of organisms. The intracisternal treatments varied from one to three in number, ranging from 4,000 to 10,000 units contained in 3 cc. of saline. Intracisternal treatment was supplemented by intramuscular injections of bacitracin varying from one to eight in number, ranging from 10,000 to 50,000 units. Intramuscular injections alone, containing 25,000 units every six hours, in four animals failed to save any of them.

These experiments indicate the trial of bacitracin by the intrathecal route in patients with meningitis due to organisms susceptible to bacitracin.

Parenteral Bacitracin in Surgical Infections. ALFRED B. LONGACRE, ROBERT M. WATERS, and FLORENCE EVANS. Department of Surgery, Louisiana State University, School of Medicine, New Orleans, La.

Bacitracin is an antibiotic derived from the Tracey strain of *Bacillus subtilis*. It exerts its greatest antibiotic action against species and strains of Gram-positive cocci. However, it is also an effective antibiotic against the clostridia organisms and also many strains of spirochetes including *T. pallidum*. As with the other antibiotics its full range of antibiotic activity will only be determined by further investigation of its inhibiting action on various strains of bacteria.

In this study of 50 cases of infection, bacitracin was an effective therapeutic agent in 33 or 65 per cent of the cases. It was administered parenterally in varying doses, ranging from 2,000 to 52,000 units every six hours. Some of the cases also received bacitracin locally in addition to the parenteral dose. The types of infection studied include those of cellulitis, deep tissue abscesses, infected wounds, furuncles and carbuncles, human bite and other miscellaneous infections. All bacteria recovered from the infections were tested for bacitracin sensitivity. In 25 instances the flora contained at least one bacitracin-sensitive organism and in this group 19 or 76 per cent responded favorably, whereas in the group of eight cases with only resistant strains, only three or 37.5 per cent had a favorable response. There were 16 cases, mostly those of cellulitis, from which no cultures were obtainable. In this last group 12 or 75 per cent had an excellent or good response.

The usefulness of parenteral bacitracin is at present restricted because of its toxic reactions. In this series, 16 cases demonstrated changes indicative of a possible lower

nephron syndrome. However, in only two instances were these changes of sufficient magnitude to be considered serious, and in no instance did a reaction persist after cessation of administration of the antibiotic. The exact factor responsible for these reactions is not known but the accumulated evidence suggests that it probably is not in the bacitracin itself but is a part of the mixture. The incidence of reactions varied with the different lots of bacitracin and did not appear to vary with the size of the dose or type of infection.

Even though 50 cases is a very small number of cases, the clinical response in those responding favorably indicates that bacitracin is an antibiotic of definite therapeutic value in cases which are caused by bacteria sensitive to it.

The Use of Aerosporin in Specific and Non-specific Enteritis in Infants and Children. FREDERIC G. BURKE, SIDNEY ROSS, E. CLARENCE RICE, and JOHN A. WASHINGTON. Children's Hospital, Washington, D. C.

Forty cases of enteritis were treated with aerosporin. These included 18 cases of non-specific enteritis, 16 cases

of shigella, 40 cases of salmonella enteritis and two cases of typhoid fever. The dose employed was 2 to 3 mgms. per kg. of body weight every four hours by mouth for seven to 15 days. The aerosporin sensitivity ranged from 0.02 to 0.08 μ g. per ml. Within 4° to 72 hours there was a marked diminution of the stool bacterial flora but no particular benefit was noted throughout the course of the non-specific diarrhea. In 14 of the 16 shigella cases a cure was noted and in two no significant effect was observed.

The value of aerosporin in salmonella was equivocal and the drug was given intramuscularly and by mouth. Toxic manifestations intervened in two of the cases and precluded adequate evaluation. There was no striking effect of the drug in the two cases of typhoid fever.

Following intramuscular injection toxic reactions included local pain, fever, malaise, and leukocytosis. Nephrotoxic reactions were noted in cases given the drug by mouth and intramuscularly and consisted of azotemia, albuminuria, white cells and casts in the urinary sediment. The high incidence of toxic manifestations of the drug would preclude its widespread usefulness.

THE SERUM PROTEINS IN INFECTIOUS MONONUCLEOSIS. ELECTROPHORETIC STUDIES

By KENNETH STERLING¹

(From the Department of Medicine, the University of Chicago)

(Received for publication February 17, 1949)

Previous investigations have shown the very frequent occurrence in infectious mononucleosis of abnormal findings on liver function tests (1-7), and of hepatic involvement on histologic examination of both autopsy (8-11) and biopsy material (1, 12-14) in cases with and without jaundice.

Alterations observed in the composition of the serum proteins (2, 4, 6, 15, 16a) appear to be compatible with the occurrence of positive cephalin-cholesterol flocculation and thymol turbidity

tests, notwithstanding the various interpretations advanced to explain the mechanisms of these tests (16-22).

The present work was undertaken to study in detail the serum proteins in infectious mononucleosis by the electrophoretic method and to examine separated protein fractions for the presence of heterophile antibodies.

METHODS

The electrophoretic runs were performed with the standard apparatus and technique described by Longworth (23) using sodium diethylbarbiturate (veronal)

SEPARATION OF SERUM PROTEIN FRACTIONS

The four samples obtained from each serum were: (1) separated albumin, (2) serum without albumin, (3) serum without gamma-globulin, (4) separated gamma-globulin.

FIG. 1

The albumin peaks are indicated by "A"; the alpha-1, alpha-2, beta, and gamma globulins are designated by their respective Greek letter prefixes. The unlabeled peaks at the beginning of the run are not protein components but are entirely normal human body fluids. The sharp peak reaching to top of the graph is due to the starting fluid. The peak at the end of the run occurring at the level of the capillary after the run is due to the starting fluid.

FIG. 1a. CONCENTRATION DIAGRAM OF SERUM COMPONENTS IN CELL AFTER ELECTROPHORESIS *

Buffer salt concentration is designated by "i," albumin by "A," and the alpha-1-, alpha-2-, beta-, and gamma-globulins by their respective Greek letter prefixes.

The solid line curves indicate the concentrations of components. The dotted lines are outlines of electrophoretic patterns as photographed, and show refractive index gradients caused by the components. Since the dotted lines represent the slopes (first derivatives) of the solid line curves, the areas under the peaks of the electrophoretic patterns give the relative concentrations of protein constituents.

buffer of pH 8.6 and ionic strength 0.1. After dialysis against the buffer the serum was diluted with buffer solution to four times its original volume prior to dialysis.

Electrophoresis was carried out at approximately 1.5°C. for 120 minutes at a potential gradient of 7.7 volts per centimeter. Photographs were taken by the schlieren scanning method.

In the estimation of the fractions as per cent of the serum proteins both ascending and descending patterns were used, the areas being divided by ordinates from the nadirs between peaks to the base line. The quantities of the fractions as grams per cent represent the products (24) of the percentages and the total proteins from the conventional Kjeldahl method, neglecting recent theoretically valid refinements (25, 26).

The separation of fractions was carried out by means of a capillary pipette lowered into the electrophoresis cell by rack and pinion. In this manner four fractions were obtained. From the ascending limb the *separated albumin* layer above the other components was aspirated. The pipette tip was then lowered further into the cell to a point just above the start of the ascending gamma-globulin peak and a sample was drawn off containing all components except gamma-globulin (*serum without separated albumin*). From the upper part of the descend-

ing limb *separated gamma-globulin* was obtained. Lowering the pipette tip to a point just above the start of the descending albumin peak yielded a sample with all components except albumin (*serum without albumin*). All these collections were performed with careful visualization of the peaks and pipette tip by the cylindrical lens method and schlieren band method when needed. After the removal of each sample a photograph was taken to show the remaining undisturbed pattern as a check on the level of the pipette tip during collection and as an indication of the accuracy of the separation. (See Figures 1 and 1a.)

In a few instances the attempt was made to verify further the accuracy of separation by reanalyzing fractions electrophoretically in the micro-cell. (See Figure 2.)

Heterophile antibody titration (27) was done on the four fractions obtained from each serum, and also on the dialyzed buffer diluted serum (not subjected to electrophoresis) which served as a control. The titres are reported as "final serum dilutions" considering the samples of fractions or controls as representing the "undiluted serum"; actually the controls were 1:4 dilutions, and the fractions were still further diluted to an indeterminate extent because of unavoidable dilution with buffer in the separation of fractions.

Absorption of heterophile antibodies was carried out by repeated incubation of inactivated serum with packed sheep red cells.

* Diagram from Moore, D. H., and Abramson, H. A.: Electrophoresis, to appear in Medical Physics (ed., O. Glasser), McGraw-Hill Year Book Publishers, Inc., 1947, vol. 2.

CASE MATERIAL

As normal controls the fasting sera of ten volunteer medical students and physicians were examined.² All were normal with respect to total proteins, albumin and globulin, alkaline phosphatase, bromsulfalein retention, hippuric acid excretion, prothrombin time, cephalin-cholesterol flocculation and thymol turbidity tests.

Seven hospitalized cases of infectious mononucleosis where the diagnosis was considered certain were selected for study. All exhibited definite enlargement of lymph nodes as well as other suggestive clinical manifestations. At some time during the hospital course each patient showed lymphocytosis as high as 50% or greater, including cells considered characteristic of the disease. Heterophile antibody titres of 1:512 or higher were present in all cases.

Two patients (T. S. and L. M.) had moderate jaundice, and one (R. S.) had slight jaundice, subsiding at the time his serum was studied. The serum bilirubin was normal in the other four cases.

To compare the findings with those in infections of approximately similar severity but without known hepatic disorder, two hospitalized cases of upper respiratory tract infection were chosen at random: one beta-hemolytic

² These sera form part of a larger study of liver disease being done in collaboration with Drs. William E. Ricketts, Joseph B. Kirsner, and Walter L. Palmer.

MICRO-CELL ELECTROPHORESIS

FIG. 2

streptococcal pharyngitis and one "acute upper respiratory tract infection, type unspecified," both with negative heterophile antibody determinations and thymol turbidity tests.

For comparison with known hepatic disease the following three cases² were studied:

- C. G., subsiding infectious hepatitis followed with serial punch biopsies of the liver;
- E. H., fatal hepatitis of probable virus etiology with progressive downhill course characterized by jaundice, edema, ascites, and hemorrhagic phenomena, and showing at autopsy massive hepatic necrosis with regeneration of pseudolobules;
- M. S., Laennec's cirrhosis with jaundice, ascites, and edema, the diagnosis being confirmed by liver punch biopsy.

RESULTS

Normal Sera

The electrophoretic and chemical data on the serum proteins of the ten normal volunteers with negative liver function tests are listed in Table I. The findings are comparable with those of other workers.

Infectious Mononucleosis Sera

The electrophoretic and chemical data on the serum proteins of the infectious mononucleosis patients with results of simultaneous liver function tests are listed in Table II.

In both the per cent compositions and the absolute amounts there were diminutions of the albumin fractions and elevations of the gamma-globulin fractions as compared with the normal sera. These deviations appear to be significant in all but the non-jaundiced patient D. C. who was also the only case with negative cephalin-cholesterol flocculation and thymol turbidity tests, and in whom the only normal alkaline phosphatase occurred among the six determinations done. The studies on this patient were done on the 24th day of illness when he had become afebrile three days before discharge.

Less pronounced and less frequently observed alterations were the elevations of the alpha-1-globulin and beta-globulin fractions.

The jaundiced cases, T. S. and L. M., exhibited somewhat more pronounced changes in serum protein composition than most of the non-jaundiced cases, but the non-jaundiced patient G. H. showed the most abnormal patterns of all, as well as the highest thymol turbidity. It will be noted from Table II that the two patients who were studied a second time, ten days later, had less

jaundice and other clinical symptoms were subsiding, but the abnormalities of the serum proteins and liver function tests were still present.

Upper Respiratory Tract Infections

There were no significant deviations from normal in the per cent compositions of the serum proteins in the two hospitalized cases of upper respiratory tract infection.

The albumin depression and gamma-globulin elevation were least pronounced in C. G., the case of subsiding infectious hepatitis, where the abnormalities were somewhat less marked than in most of the infectious mononucleosis cases. These deviations from normal were more pronounced in E. H., the case of fatal hepatitis, and were most striking in M. S., the case of Laennec's cirrhosis, where the gamma-globulin actually exceeded the albumin.

	Albumin	α_1 -glob.	α_2 -glob.	β -glob.	γ -glob.	A/G ratio
Beta-hemolytic streptococcal pharyngitis	58.0%	5.2%	10.6%	11.6%	14.6%	1.38
Upper resp. tr. infect., type unspecified	62.9%	4.3%	8.7%	11.5%	12.6%	1.70

Known Hepatic Disease

The findings in the three cases of histologically proven liver disease are shown in Figure 3, together with data from normal and infectious mononucleosis sera.

Heterophile Antibody Titres of Separated Fractions

After electrophoresis each infectious mononucleosis serum was separated into the following four fractions:

1. *Separated albumin*
2. *Serum without albumin*
3. *Serum without gamma-globulin*
4. *Separated gamma-globulin.*

The dialyzed buffer diluted serum (not subjected to electrophoresis) served as a control.

The results of the heterophile antibody titrations are listed in Table III. The figures express "final serum dilutions," considering the samples of fractions or controls as representing the "undiluted serum"; actually the controls were 1:4 dilutions and the fractions were still further diluted to an indeterminate extent.

As shown in Table III, heterophile antibodies were demonstrated in the *separated gamma-globulin* in every case, and were never present in the *separated albumin*. Heterophile antibodies were absent from the *serum without gamma-globulin* in seven of the ten experiments recorded, but present in three.

The low titres in the *separated gamma-globulin* samples in comparison with the controls were presumed due to the unavoidable dilution in the process of fractionation. To test the supposition that these samples contained minute amounts of protein, micro-Kjeldahl determinations were done on three samples of *separated gamma-globulin* with the following findings (after subtraction of buffer nitrogen):

T. S., 12th day—30.8 mg. nitrogen per 100 cc.
D. C., 24th day—22.4 mg. nitrogen per 100 cc.
M. W., 11th day—18.2 mg. nitrogen per 100 cc.

Assuming a nitrogen factor of 6.25, these samples contained approximately one-tenth to one-seventh the gamma-globulin concentration of their respective undiluted whole sera.

Attention was directed toward the occurrence of heterophile antibodies in a few of the samples of *serum without gamma-globulin*. It was suspected that the separations might not be accurate, but

to repeat the original experiment, serum from the 12th day was used instead, with similar findings. This duplication of results also argues against technical error in the separation.

As a further check, micro-cell electrophoretic runs (see Figure 2) were performed on the three samples in question. Because part of each sample (already dilute) had been used for heterophile antibody titration, it was necessary to add buffer to obtain the 2 cc. required for a micro-cell run. Consequently, the peaks were quite low and the patterns could be interpreted as no more than suggestive evidence of the absence of gamma-globulin.

Absorption of Heterophile Antibodies

By absorption with sheep red cells the heterophile antibody titre of the serum of G. B. (19th day of illness) was reduced from 1:2048 to 1:32.

The electrophoretic patterns before and after antibody absorption were practically identical.

DISCUSSION

The serum protein compositions of the infectious mononucleosis patients showed definite diminutions of the albumin fractions and elevations of the gamma-globulin fractions as compared with normal sera. Less pronounced and less frequently observed deviations from normal were the elevations of the alpha-1-globulin and beta-globulin fractions.

The cases studied were limited to hospitalized patients in whom the diagnosis could be made with certainty; it cannot be asserted that an unselected series would necessarily have shown as pronounced changes.

Numerous investigators have observed generally

	Albumin	Alpha-1	Alpha-2	Beta	Gamma
Before absorption (titre 1:2048)	43.4%	8.0%	17.1%	10.7%	20.8%
After absorption (titre 1:32)	43.2%	7.7%	18.1%	10.5%	20.5%

similar if more conspicuous abnormalities in hepatitis and cirrhosis (16, 18, 28-33). As suggested by Figure 3 these changes in infectious mononucleosis may bear some relationship to the type if not the degree of hepatic dysfunction.

The cephalin-cholesterol flocculation and thymol turbidity tests may merely reflect directly the abnormalities of the serum proteins (16-22). The concomitance, however, of occasional hyperbilirubinemia, frequent elevation of alkaline phosphatase activity (2, 5, 6), and histopathologic evidence of liver involvement (1, 8-14) makes plausible the association of disturbed hepatic function and the alterations of the serum proteins. Such a conception is not in any sense incompatible with the probable extra-hepatic *origin* of serum globulins.

That the widespread pathologic involvement of the lymph nodes and the foci of mononuclear cell infiltration in various organs may be directly responsible for changes in the serum proteins is an attractive hypothesis. This idea has been advocated on the basis of electrophoretic findings in infectious mononucleosis and the blood dyscrasias, the latter group exhibiting rather varied alterations (15).

The possibility that the changes in the serum proteins in infectious mononucleosis may be related to the infectious process *per se* deserves consideration in the light of somewhat similar abnormalities described in infectious diseases such as syphilis, tuberculosis, typhus, malaria, lymphogranuloma venereum, leprosy, kala-azar, and others (34). It must, however, be noted that most of the above conditions are characterized by chronic proliferative granulomata or by widespread cellular destruction, hence are not too closely analogous to infectious mononucleosis. On the other hand, in lobar pneumonia there are conspicuous elevations of the alpha-2-globulins usually without significant changes in the gamma-globulins (34, 35).

In an effort to compare the findings in infectious mononucleosis with those in infections of approximately similar severity but without known hepatic disorder, the sera of two hospitalized cases of upper respiratory tract infection were analyzed electrophoretically with the finding of normal patterns. It would appear that the extent to which the serum protein changes are attributable to

the non-specific effects of the infectious process is debatable.

That the gamma-globulin increase could be due to the heterophile antibodies is excluded by the experiment showing no change in electrophoretic pattern after antibody absorption. In other human diseases absorption of clinically important specific antibodies has produced no change in electrophoretic pattern, the antibodies being present in too small quantities to cause visible alterations in schlieren patterns even though easily detectable by serological methods (34, 36). Immuno-chemical studies corroborate the minute concentrations of antibodies in human serum (37).

The data on the distribution of heterophile antibodies in relation to the serum protein fractions are interpreted as indicating that they are predominantly in the gamma-globulin fraction, not always being exclusively confined to this fraction.

The occurrence of various antibodies in the gamma-globulin fractions of animals has been demonstrated repeatedly (37, 38) since the original work of Tiselius and Kabat (39) showing pneumococcal antibodies in the gamma-globulins of rabbit and monkey sera. It must, however, be recalled that Tiselius and Kabat found in the horse that pneumococcal antibodies migrated between the beta- and gamma-globulins forming a separate peak. Since then equine antibodies to diphtheria toxin, tetanus toxin, and others have been found outside the gamma-globulin fraction (37, 38). Virus-neutralizing antibodies to Venezuelan and Western equine encephalomyelitis have been demonstrated in both the beta- and gamma-globulins of rabbit sera (40).

The extensive work of Enders (41) on the products of human plasma fractionation revealed that Fraction II, composed of almost pure gamma-globulin, contained in high concentration antibodies reacting with diphtheria toxin, streptococcal erythrogenic toxin, influenza A virus, mumps virus, and the H-antigen of *E. typhosa*. On the other hand, isoagglutinins and antibody reacting with the O-antigen of *E. typhosa* were recovered from Fraction III-1, containing mostly beta-globulin and less gamma-globulin. Furthermore, smaller amounts of the antibodies concentrated in Fraction II were found in other fractions free of gamma-globulin. Subsequently, division of human gamma-globulin into sub-fractions with differ-

ing antibody contents has been reported (42).

Electrophoretic separation of sera from allergic patients has suggested that ragweed and rabbit antibodies (or reagins) are confined to the gamma-globulin fraction (43).

In a study employing electrophoretic, ultracentrifugal, and immuno-chemical methods the Wassermann antibody (or reagin) has been clearly shown to have a mobility intermediate between beta- and gamma-globulins and overlapping both (44).

It is hoped that the present findings on heterophile antibodies in infectious mononucleosis will be supplemented by further physico-chemical studies.

SUMMARY

1. Electrophoretic analyses of the serum proteins of seven cases of infectious mononucleosis revealed deviations from the normal composition in both jaundiced and non-jaundiced patients.

2. The principal abnormalities observed were diminutions of the albumin fractions and elevations of the gamma-globulin fractions.

3. Less pronounced and less frequently observed alterations were elevations of the alpha-1-globulin and beta-globulin fractions.

4. Liver function tests showed abnormalities in six of the seven cases.

5. The alterations of the serum proteins were considered as possibly related to hepatic dysfunction, among other hypotheses entertained.

6. Separation experiments indicated the heterophile antibodies were contained predominantly in the gamma-globulin fractions of the sera, not always being exclusively confined to this fraction.

ACKNOWLEDGMENTS

The author wishes to express gratitude for being permitted to use the electrophoresis apparatus in the laboratory of Dr. E. S. Guzman Barron, and for generous help in heterophile antibody determinations by Miss Isabelle Havens.

EVIDENCE THAT RENAL SODIUM EXCRETION BY NORMAL HUMAN SUBJECTS IS REGULATED BY ADRENAL CORTICAL ACTIVITY¹

By ALEXANDER LEAF AND WILLIAM T. COUTER

WITH THE TECHNICAL ASSISTANCE OF MARION LUTCHANSKY AND ANN REIMER

(From the Department of Internal Medicine, The Medical School, University of Michigan, Ann Arbor, Mich.)

(Received for publication February 25, 1949)

When a normal human being is placed on a very low sodium intake, the urinary sodium decreases to very small amounts. Contrariwise, with large sodium intakes, the urinary sodium increases proportionately. In both cases, the normal body content of sodium is quickly reestablished. How is this conservation of body sodium effected?

The depletion of body sodium that occurs in adrenalectomized animals and in patients suffering from Addison's disease, and the retention of sodium with reestablishment of balance that accompanies the administration of adrenal cortical extracts, leaves no doubt about the fundamental position of a cortical hormone in the regulation of body sodium in the abnormal states just mentioned (1-5).

Since there is a paucity of information regarding the regulation of body sodium content in normal subjects who receive large variations in intake of sodium, our studies were designed to learn the role of adrenal cortical activity in this regulation in normal human beings.

Even though it is not possible to determine directly the concentration of the specific hormone in the blood, nevertheless a number of methods that serve as indirect indices of adrenal cortical activity are available. It was surmised that by creating a need to conserve body sodium in the presence of large shifts in intake, evidence of other adrenal cortical effects, especially on protein metabolism, might be elicited. If such evidence of adrenal cortical activity can be obtained by the requirement to conserve sodium, such data would greatly strengthen the hypothesis that in the normal subject this conservation of body sodium is in fact mediated through an increased or decreased adrenal cortical activity (6).

EXPERIMENTAL

Three normal young adults were subjects for this study: one male resident physician (W. C.), age 32; one male medical student (E. W.), age 22; and one female graduate student (M. L.), age 22. The plan of study was to place the subject on an adequate caloric and protein dietary intake with a very low sodium content (approximately 200 mgs. or 9 mEq. daily) throughout the study, and at definite periods to administer orally large amounts of sodium as sodium chloride or sodium citrate.

This was accomplished by using a constant daily diet. The water intake was uncontrolled as its sodium content was found to be insignificant by analysis. The subjects went about their usual daily activities avoiding severe exertion and sweating. Urine and stool collections were made daily and the nude body weight was recorded each morning before breakfast and after emptying the bladder. A special human balance having a sensitivity of 5 gms. was used. Each 24 hour urine was collected with toluene as a preservative and was analyzed separately on the day following the collection. Stools were promptly treated with alcohol and made acid with glacial acetic acid or sulfuric acid, dried in an oven at 50° to 60° C., weighed, blended in a Waring blender and combined into two or three day periods with suitable aliquots taken for analyses. Subjects were fed from the same lot of food throughout the period of study and a sample day's diet was dried, blended and analyzed.

When a constant body weight was achieved and the urine sodium and chloride excretions had reached a minimum on this low sodium intake, 11.0 gms. or 478 mEq. of sodium were administered orally as the chloride (28.0 gms. of sodium chloride) or citrate (46.6 gms. of sodium citrate) daily for three days. Fasting blood samples were obtained with a minimum of stress at the beginning and end of the study, and before and after each period of sodium administration. Samples for potassium and carbon dioxide content were drawn under rest and the former kept refrigerated until the serum was separated from the cells with no hemolysis occurring.

Hematocrit (packed red cell volume) was estimated by the method of Wintrobe (7). Sodium analyses were done on serum, urine, diet, and stool by means of the Butler and Tinsall (8) modification of the flame photometric method of Butler and Tinsall (8). For sodium of very low sodium content a modification was made by using

¹ This study was aided by a grant from the United States Public Health Service.

aliquots and removal of potassium as well as phosphate was utilized (9). Potassium was determined in serum, urine, diet and stool by a modification of the platinum chloride micro colorimetric method of Shohl and Bennett (10). Chloride analyses of serum were done using the method of Van Slyke and Sendroy (11). Urine, stool, and diet chloride determinations were done by a modification of the Volhard-Harvey titration (12). Urinary ammonia was determined by the aeration method of Van Slyke and Cullen (13). Total urine, diet and stool nitrogen were determined by the Kjeldahl method for macro analysis (14). Urine creatinine was measured by the alkaline pierate method of Folin (15) and in subject E. W., also by the modification of Bonsnes and Taussky (16). Agreement between the very simple method of Folin and the more refined latter method was surprisingly good. The modification of Bonsnes and Taussky was also adopted for serum creatinine determinations. Blood urea nitrogen was estimated by the method of Gentzkow (17) while for urine urea the method of Barker (18) was utilized. Urine uric acid determination was done by the total color method of Buchanan, Block, and Christman (19). Carbon dioxide content of the serum was determined by the method of Van Slyke and Neill (20). Serum protein analyses were done by the micro Kjeldahl method and the steam distillation of Goebel (21). Urine, stool and diet were analyzed for phosphate by the colorimetric method of Fiske and Subbarow (22).

The aliquots of diet and stools were dry ashed in such a manner that analyses could be made for sodium, chloride, potassium, and phosphorus on a single preparation. This was accomplished by mixing the aliquot with an excess of calcium hydroxide until definitely alkaline, drying and then ashing in the muffle furnace at 400° C. for 48-72 hours. The residue was washed with water and filtered. The filtrate containing the sodium, chloride, and potassium was made up to volume in a volumetric flask from which aliquots were taken for analysis. The washed residue was later dissolved with dilute nitric acid to yield phosphate. Values for chloride of diet and stool obtained by this method were the same as values obtained by wet ashing the sample.

Inulin clearances were done by the Harrison modification of the method of Alving, Rubin, and Miller (23) following a single intravenous injection of 10-20 gms. of inulin.

The values for dietary intake of calories, carbohydrate, fat and protein were obtained from Bowes and Church (24) and U. S. Department of Agriculture Circular Number 542. The calculated values for sodium, chloride, potassium and phosphorus content of foods were obtained from McCance and Williamson (25). In addition, analyses were made on complete diets (with the exception of the latter for total nitrogen, total phosphorus, sodium, chloride, and potassium). The agreement between actual analyses and calculated values was surprisingly good. This in subject M. L.'s diet the calculated and analyzed composition was respectively: nitrogen—12.3 and 11.2

gms.; sodium—8.7 and 8.3 mEq.; chloride²—21.0 and 22.8 mEq.; and potassium—89.7 and 94.0 mEq. Similarly in subject E. W.'s diet the calculated and analyzed composition was respectively: nitrogen—14.3 and 15.0 gms.; sodium—9.1 and 9.4 mEq.; chloride—24.4 and 24.9 mEq.; and potassium—100 and 100 mEq. The dietary intake figures recorded for subjects M. L. and E. W. in Tables II and III are values obtained by our analyses for sodium, chloride, nitrogen, potassium and phosphorus as no diet changes were made and all the food was eaten. In subject W. C. who frequently rejected portions of his diet, such portions were weighed and their composition as obtained from the above-mentioned food composition tables was subtracted from the total calculated content of the diet, and each day's intake is recorded in Table I.

RESULTS

The complete data of these studies are shown in Tables I, II and III.

The electrolyte and weight changes are the subject of a separate report (6). However, it is important to the present discussion to point out that with the curtailment of sodium intake to about 9 mEq. daily there occurred a sharp initial weight loss of about 2 kilograms in each subject. This weight loss was associated with a negative sodium and chloride balance (Figure 1 illustrates these changes in subject E. W.). After approximately one week of this low sodium regimen the urinary loss of sodium and chloride was reduced to extremely minute amounts (1 to 2 mEq. of sodium in the 24 hour urine specimen) and the weight became stabilized. Under the stimulus of such severe sodium restriction the kidneys conserve sodium maximally.

On administration of the large amounts of sodium (480 mEq. daily for three days) as the sodium chloride or sodium citrate salts there was with each a significant weight gain. None of the subjects showed clinical edema, however. The urinary excretion of sodium lagged in every case so that only by the last day of the sodium administration had the output attained the daily intake level.

With these changes in weight and in urinary excretion of sodium and chloride, accompanying

² Interestingly the diet analyses, not including "Lonac," yielded nearly equivalent values for sodium and chloride. The addition of "Lonac" (Mead Johnson and Co., Evansville, Indiana), which contains supplementary potassium chloride, resulted in the actual higher values of chloride.

Dietary intake was constant daily and consisted of: calories 3225, nitrogen 15.0 gms., sodium 9.4 mEq., chloride 24.9 mEq., potassium 100.1 mEq., and phosphorus 49.8 mEq.

FIG. 1. To SHOW CHANGES IN BODY WEIGHT, SERUM SODIUM AND CHLORIDE CONCENTRATIONS, AND SODIUM BALANCE IN SUBJECT E. W.

changes were noted in extracellular fluid composition. The sodium restriction uniformly caused a small but significant lowering of serum sodium concentration and elevations occurred on administration of sodium. Serum chloride values followed a similar trend though less uniformly. Administration of the sodium citrate caused a rise in serum sodium in each case, a decrease in serum chloride in two cases and a rise in serum CO_2 content. A parallel rise in serum sodium and chloride followed sodium chloride administration. With the sodium citrate administration urinary sodium excretion rose sharply to high levels but urinary chloride loss was, if anything, further decreased. This is additional evidence that the kidneys can deal separately with these two most important ions of the extracellular fluid.

There is slight variability in stool sodium and chloride excretion. But considering the drastic changes in oral sodium and chloride intake from about 10 to 500 mEq. daily the stool losses remained surprisingly fixed and insignificantly small.

Fecal potassium excretion also showed no noteworthy variation.

Subject W. C. had one loose stool associated with abdominal cramps on the last day of sodium chloride administration. This one stool was collected and analyzed separately. Its sodium and chloride content was much higher than the remaining stools of that period.

Of greatest importance to this discussion are the observed changes in protein metabolism that occurred with variation of sodium intake. Figure 2 shows graphically the changes in nitrogen balance, urine urea excretion, blood urea nitrogen concentration, urine total uric acid excretion, urine potassium and phosphorus excretions in subject E. W. Exactly similar changes were observed in our other two subjects but because data are more complete in our last study on E. W. his results have been graphed. Sodium restriction is shown to produce slightly negative nitrogen balance during the first low sodium period. Following both periods of sodium administration the urine plus fecal nitrogen is considerably

FIG. 2. TO SHOW CHANGES IN NITROGEN BALANCE, 24 HOUR URINARY UREA, URIC ACID, POTASSIUM, PHOSPHORUS EXCRETIONS AND BLOOD UREA NITROGEN CONCENTRATIONS IN SUBJECT E. W.

The days of sodium chloride and sodium citrate administration are noted between parallel vertical lines. The hatched areas under "fecal N" are values obtained by actual analysis of feces for total nitrogen content; the remainder of "fecal N" is estimated.

less than the intake of nitrogen so that nitrogen is stored in the body. The fecal nitrogen reveals that this decreased urinary nitrogen excretion was not the result of impaired nitrogen absorption from the alimentary tract.

Creatinine and ammonia excretion remained essentially constant so that the changes in urinary nitrogen excretion could be expected to be the result of changes in "metabolic" nitrogen. The urine urea excretion is seen to confirm this expectation since all changes in total urinary nitrogen are due almost entirely to changes in urine urea nitrogen (the difference between total urine nitrogen and urine urea nitrogen remaining very constant throughout the study).

That the changes in total and urea nitrogen excretion are not simply the result of storage of urea in the body fluids is indicated by the dramatic changes seen in the blood urea nitrogen. At the time when the urinary excretion of urea is at its lowest the blood urea concentrations are likewise lowest. Correcting the blood urea concentration for the dilution that might occur as the result of the increased body fluid volume produced by the sodium administration causes only insignificant changes. The serum creatinine was measured in the subject E. W. and though it shows minor fluctuations it in no way parallels changes in blood urea level. It has been amply proven that the serum creatinine concentration is independent of the level of protein catabolism (26). As there has occurred no impairment of gastrointestinal absorption of nitrogen these changes can be interpreted only as the result of a decreased rate of urea production or a decreased catabolism of protein associated with administration of sodium to individuals previously maintained on low sodium diets. These effects on protein metabolism occur following both sodium citrate and sodium chloride administration and therefore are the result of the sodium rather than of the accompanying anion.

Urine uric acid excretion, urine potassium and phosphorus excretion mimic the changes in nitrogen metabolism exactly except for the very high rate of potassium excretion on the first day of sodium citrate administration. This change is believed to be due to effects other than those on protein metabolism (6). Serum potassium concentrations failed to show any evidence of increasing

with the periods of low urine potassium excretion though unfortunately no serum potassiums were taken on the third or fourth days after the high sodium periods when this effect might have been present.

A point to be stressed is that there occurred a definite lag in the renal excretion of sodium during each high sodium period. Not until the third and last day of each high sodium period did the urinary excretion reach the level of the intake. Our interpretation of this lag is discussed below but here it should be noted that all the effects associated with the depressed protein catabolism were most pronounced immediately following rather than during the periods of high sodium administration, thus paralleling in this respect the lag in sodium excretion.

Urines were tested daily for reducing substance by the qualitative Benedict's test on subjects M. L. and E. W. but no evidence of glycosuria was noted. Glucose tolerance tests were done on subjects M. L. and E. W. M. L. showed no evidence of impaired glucose tolerance on the 11th day of the low sodium intake. (Standard glucose tolerance test after 1.75 gms. of glucose per kilogram of body weight revealed: fasting blood sugar—75 mgs.%; one hour—71 mgs.%; two hours—82 mgs.%; three hours—51 mgs.%; four hours—56 mgs.%.) E. W. on the 12th day of the final low sodium intake period showed: fasting blood sugar—89 mgs.%; after one hour—160 mgs.%; second hour—100 mgs.%; third hour—56 mgs.%. A repeat glucose tolerance test on E. W. two months after completion of this study and while on a normal dietary sodium intake revealed: fasting blood sugar—81 mgs.%; after one hour—153 mgs.%; after two hours—100 mgs.%; and after three hours—64 mgs.%.

DISCUSSION

Changes in nitrogen metabolism similar to those reported here have been noted by others. In studying experimental sodium deficiency produced by a low sodium intake and sweating in normal subjects McCance (27) found that his subjects developed negative nitrogen balances with rise in blood urea concentration. This observation was striking enough to be emphasized by the author. In a subsequent publication, McCance and Widdowson (28) conclude that the main cause

of this elevation of blood urea concentration with sodium depletion is the associated reduction in glomerular filtration rate. In another study McCance (29) observed that the administration of large doses of sodium chloride and sodium bicarbonate depressed the serum urea concentration significantly in previously dehydrated subjects. The electrolyte balance study of Albright and Bauer (30) on an edematous nephritic likewise shows an effect of administered sodium chloride and sodium bicarbonate on the nitrogen balance. Both sodium salts produced positive nitrogen balance. Landis *et al.* (31) reported striking changes in blood urea nitrogen levels in three subjects with varying degrees of renal insufficiency when the daily amount of sodium chloride intake was altered. Sodium chloride restriction caused increased blood urea nitrogen concentrations while administration of this salt lowered the concentration. These workers did 24 hour urea and creatinine clearances finding some increase in these clearances during the periods of sodium chloride administration. The decrease in blood urea nitrogen with administration of sodium chloride was associated with the increased renal clearances.

It is to be expected that administration of sodium chloride will increase glomerular filtration rate and hence urea clearance. Contrariwise, restriction of sodium intake in non-edematous patients with renal insufficiency is likely to produce severe dehydration through excessive renal loss of sodium with shrinkage of extracellular fluid volume. Hence, the increase in glomerular filtration rate with sodium administration is especially to be anticipated in patients with renal insufficiency (as were those of Landis *et al.*) who may be dehydrated prior to administration of the sodium.

The gain in weight observed in our subjects when sodium chloride was administered was almost entirely the result of an increase in extracellular fluid volume (as calculated from the gain in "chloride space" from the observed chloride balance). In such acute experiments as ours, changes in the hematocrit reflect changes in intravascular volume. Table IV clearly shows that sodium chloride administration results in a decrease in cell hematocrit with hemodilution. This increased intravascular volume may be expected, other factors remaining constant, to increase renal plasma flow with resulting increased glomerular

TABLE IV

E. W.

Hemodilution with increased rate of glomerular filtration following sodium chloride but not sodium citrate

Day	Hematocrit	Total serum protein	24 hour creatinine clearance	24 hour urea clearance

32	48	7.10	149	82

filtration rate. Another aspect of the hemodilution is the decrease in total serum protein concentration also shown in Table IV. This decrease would cause a decreased colloid osmotic pressure of the serum which also, other factors remaining constant, would favor an increased rate of glomerular filtration. The creatinine clearance figures in Table IV taken as a measure of glomerular filtration rate (32, 33) in E. W. show this expected increase when sodium chloride is administered. An even proportionately greater increase in the 24 hour urea clearance is seen. This indicates a reduced rate of tubular reabsorption of urea in addition to the increase in glomerular filtration rate. This is to be expected with the greater rate of urine formation that followed the sodium chloride administration. Inulin clearance measurements of glomerular filtration rate in subject W. C. on the low sodium intake and immediately following the high sodium chloride period reveal exactly similar changes in glomerular filtration rate (117 cc./min. after 12 days of low sodium intake and 158 cc./min. the day after the sodium chloride administration) with the same evidence of increased plasma volume and hemodilution. Female subject M. L. however showed no significant change in inulin clearance (121 cc./min. on the ninth day of low sodium intake or 113

cc./min. and 112 cc./min. on the days following the sodium chloride and sodium citrate period respectively). She also showed much less evidence of hemodilution than did the other two subjects. Sodium citrate produced no noteworthy changes in renal clearances in any subject.

Thus sodium chloride administration may to some degree lower the blood urea concentration by producing increased renal clearances in some cases. In our normal subjects the effect of altered renal dynamics on the blood urea concentration was, however, of lesser importance. In spite of the increased urea clearance in subjects E. W. and W. C. following sodium chloride, the 24 hour urea excretion was markedly reduced. The only way an increased clearance alone can decrease blood concentrations of a substance is by an increased rate of removal of that substance from the body fluids. But our data in all cases reveal a sharp decrease in the rate of urea and nitrogen excretion just at the time of lowest blood concentrations. Sodium citrate, which failed to increase the glomerular filtration rate, also produced a depression in blood urea concentration. In subject M. L. no noticeable increase in glomerular filtration rate was apparent on the day following administration of sodium chloride. However, the blood urea nitrogen depression still occurred.

In the presence of normal alimentary absorption of nitrogen and decreased renal excretion of it, the drop in blood concentrations of urea in our subjects must have been the result of a decreased rate of catabolism of protein. This accounted for the positive nitrogen balance resulting from administration of sodium. Figure 2 clearly shows that such an interpretation is justified.

The purpose of this study was to learn whether the physiological regulation of body sodium content is controlled by adrenal cortical activity in normal persons who ingest variable amounts of sodium. It has been amply demonstrated that the adrenal cortex produces hormones which are capable of decreasing renal sodium excretion (1, 5, 34) and increasing catabolism of protein (35, 36). The former has a desoxycorticosterone-like action and has been termed the "salt-and-water" hormone (or hormones) while the latter is protein catabolic or anti-anabolic and will be called the "protein catabolic" hormone in this discussion.

This does not prove, however, that in the normal subject the desoxycorticosterone-like hormone actually controls sodium balance. But if these two apparently unrelated effects of adrenal cortical activity (*i.e.*, on sodium and on protein) are elicited by the single stimulus to conserve body sodium, this will afford good evidence that the adrenal cortex is importantly involved in regulation of normal body sodium.

With these two actions of the adrenal cortex in mind, the changes noted in Figure 2 lend themselves readily to explanation on the basis of alterations of adrenal cortical activity as follows. In the first eight days of sodium restriction renal excretion of sodium decreased to a minimum under the stimulus of increased adrenal salt-and-water hormone activity. At the same time the rate of protein catabolism resulting from increased protein catabolic hormone activity caused a negative nitrogen balance with the levels of excretion of urea, uric acid and potassium as charted. Administration of large amounts of sodium chloride on the ninth, tenth and 11th days removed the requirement for renal conservation of sodium. The adrenal responded by decreasing the activity of its salt-and-water hormone output allowing the kidneys to increase their rate of sodium excretion enormously. At the same time the protein catabolic hormone was likewise depressed with decreased protein catabolism, a positive nitrogen balance, decreased uric acid, urea, potassium and phosphorus excretions. Further sodium restriction from the 12th to 19th day resulted again in a decreased urine sodium excretion (increased adrenal activity). The following three day period of sodium citrate administration reproduces the same effects of decreased adrenal cortical function that occurred with sodium chloride administration, followed finally by increased adrenal cortical activity when sodium intake was again restricted during the final 14 days of the study.

Figure 3 was constructed from the observed potassium and phosphorus balances of subject E. W. The theoretical potassium and phosphorus balances were calculated from the observed nitrogen balance. It is noted from this figure that the decreased potassium excretion that followed each period of sodium administration can only partially be accounted for by the decreased catabolism of protein that occurred at that time. Knowing that

desoxycorticosterone, the salt-and-water hormone par excellence, produces an increased renal excretion of potassium (37, 38) while patients with Addison's disease and adrenalectomized animals have a decreased ability to excrete potassium (1, 39), this observed drop in potassium excretion is taken to be, at least in part, the result of a decreased salt-and-water hormone activity occurring at this time when there is a large renal sodium ex-

cretion. Unfortunately, the serum potassium concentration was not determined immediately following the days of lowest urinary potassium excretion to ascertain whether or not an elevation of serum potassium occurred as a result of this decreased renal potassium excretion. The strikingly negative potassium balance on the first day of sodium citrate administration is discussed in another paper (6).

FIG. 3. THE ACTUAL AND THEORETICAL POTASSIUM (LOWER) AND PHOSPHORUS (UPPER) BALANCES OCCURRING IN SUBJECT E. W.

Output values were determined from the sum of urinary and fecal contents and intake values were obtained from diet analysis. The factor 2.7 was used to convert grams of observed nitrogen balance to milli-equivalents of "theoretical potassium balance" and the factor 2.15 to convert grams of observed nitrogen balance into millimols of "theoretical phosphorous balance." Note especially the large positive actual potassium balance immediately following both periods of sodium administration.

A comparison of the phosphorus and nitrogen balances, also illustrated in Figure 3, reveals no significant differences between actual and theoretical phosphorus balance. The theoretical phosphorus balance was not, however, corrected for possible changes in bone metabolism.

Our data show more distinct evidence of depression of adrenal cortical activity with administration of sodium than stimulation of activity by restriction of sodium. However, with more severe sodium depletion produced by sweating in addition to very low sodium dietary intake, one of McCance's subjects had a negative nitrogen balance of 45 gms. in 11 days of sodium depletion and McCance states (27) ". . . this illustrated rather well the fact that the nitrogen balance steadily became more negative as sodium chloride was withdrawn from the body." Conn (40) found that sodium restriction in normal subjects undergoing acclimatization to humid heat results in negative nitrogen balance. This investigator demonstrated that it was the sodium restriction rather than a nonspecific effect of the hot environment which caused the negative nitrogen balance. Thus when acclimatization to the hot environment was complete in his subjects while they were on a fixed sodium intake, nitrogen balance was regained. Further restriction of sodium, without changing the exposure to the hot environment or otherwise altering the diet, was again followed by a negative nitrogen balance, which disappeared gradually as reacclimatization was accomplished on the lower sodium intake. Thus, it seems that the amount of evidence of increased protein catabolic hormone activity that is elicited in response to sodium restriction is dependent upon the intensity of the requirement to conserve body sodium.

It is also evident from our data that with prolongation of the period of low sodium intake the effects on nitrogen metabolism attributed to adrenal activity (protein catabolic hormone action) disappear. This occurs in spite of the continued renal conservation of sodium. In all three subjects the protein catabolic effects were most evident early in the study. As mentioned above, Conn (40) found that during acclimatization to a hot environment negative nitrogen balance occurs early and gradually disappears. It is of interest in this connection to note that Swanson and Smith

(41) found that rats kept on a "salt-free" diet showed a definite increase in weight of the adrenals followed by regression, with adrenal weights after 90 days only slightly greater than in the control rats receiving salt.

Apparently then, with continuation of the requirement to conserve body sodium, the protein catabolic hormone effect disappears. This could be the result of a decreased adrenal cortical output of protein catabolic hormones or of a decreased response on the part of the tissues to the action of an increased protein catabolic hormone in the body. Our data give no clue as to whether one of the two or both possibilities actually occurs.

A further point of interest should be mentioned. That is the definite lag that occurred in the renal excretion of sodium when it was administered to our subjects following the low sodium intake, and the lag in the renal conservation of sodium that occurred when the sodium intake was again sharply reduced. Because the changes noted in nitrogen balance and renal potassium excretion with sodium administration show exactly the same lag, it appears that the sudden changes in sodium intake require some time to produce an adrenal response.

We are well aware that this interpretation of our results suffers considerably from the lack of adrenal cortical hormone assays which would more directly define the role of the adrenal cortex.³ However at the present time there is no method of measuring directly adrenal salt-and-water hormone production. Forsham *et al.* have found increased uric acid excretion to be a more consistent and more marked result of prolonged administration of 11 and 11-17 oxycorticosteroids than is the nitrogen balance (42). Further studies by this group of uric acid excretion in response to adrenocorticotrophin administration (43) support the view that uric acid excretion reflects changes in 11-oxycorticosteroid activity. The observed changes in total uric acid excretion in subject E. W. on a constant purine diet (see Figure 2) clearly then support our interpretation of altered adrenal cortical activity in response to varying sodium intake.

³ Space does not permit a discussion of possible changes in androgenic and protein anabolic hormone activity of the adrenal cortex and our data show no positive evidence that such changes occurred.

Because evidence of both protein catabolic hormone activity and of salt-and-water hormone activity has been elicited by the need to conserve body sodium it is suggested that the adrenal received its direct stimulus via the anterior pituitary. Studies with adrenocorticotrophic hormone administration to human beings support this view since this hormone causes stimulation of protein catabolic effects as well as salt-and-water hormone effects (40, 43).

The fact that the changes observed were similar following both sodium chloride and sodium citrate administration indicates that the sodium cation is of importance rather than the anion. Just what change occurs in the body when sodium intake is restricted or high, which serves to initiate the adrenal cortical activity, is not revealed. Changes in concentration of extracellular fluid, sodium, chloride, CO_2 content, tonicity of extracellular fluid or volume of extracellular fluid perhaps through its effect on circulating intravascular volume, all suggest themselves, but a multitude of other changes which occur in the extra- and intracellular fluids with variation in sodium intake might as likely act as the actual stimulus. The work of Selye on the general adaptation syndrome (44) suggests that our observations might simply cover an adaptation to sodium restriction as the stress, but this would only further describe rather than explain our results. Our findings and interpretation are in agreement with those of Conn (40), who demonstrated an increased adrenal cortical activity in response to the requirement to conserve salt during acclimatization to humid heat.

SUMMARY AND CONCLUSIONS

Some effects of marked variation in sodium intake in three normal young adult subjects were studied. These subjects were maintained on fixed diets containing adequate calories and protein with very low sodium and chloride content. At definite periods the sodium intake was abruptly increased by the addition of 480 mEq. of sodium as sodium chloride or sodium citrate.

With reduction from usual intakes of sodium to 9 mEq. of it daily there occurred an initial negative balance of sodium and chloride followed by progressive reduction of urinary losses to minimal amounts in about five days. This initial loss of body sodium and chloride was associated with a

loss of about 2 kilograms of weight with subsequent stabilization of weight as urine sodium and chloride loss became very small. Slight decrease in serum sodium and chloride levels also occurred.

Administration of sodium as sodium chloride or as sodium citrate was accompanied by a sharp increase in body weight much more pronounced with sodium chloride than with the citrate. There also occurred a hemodilution as evidenced by decrease in serum proteins and hematocrit and an increased glomerular filtration rate. These latter effects were much more pronounced after sodium chloride administration than after sodium citrate.

A definite lag in the renal excretion of sodium with the shift from the low to the high sodium intake and a delay in the renal conservation of sodium with change from the high to the low sodium intake occurred.

With this variation in sodium intake definite changes in protein metabolism occurred. Administration of sodium after sodium restriction produced positive nitrogen balance while sodium restriction increased the rate of protein catabolism. These changes were reflected in increased 24 hour urea, uric acid, phosphorus and potassium excretions with sodium restriction and depression of these urinary excretions with sodium administration. In addition a definite decrease in blood urea concentration occurred with each period of sodium administration which could not be accounted for by alteration in renal clearance of urea but was the result primarily of a decrease in the rate of protein catabolism.

The decreased urinary potassium excretion following the periods of sodium administration could not be entirely accounted for by the decrease in protein catabolism that also occurred at this time and this effect is discussed.

We believe that all the observed effects are best explained by changes in adrenal cortical activity. In this sense the requirement for conservation of body sodium in the presence of a very low sodium intake was met by increased adrenal cortical activity of a desoxycorticosterone-like hormone, accompanied by increase in activity of adrenal protein catabolic hormone. Administration of large quantities of sodium abolished this need to prevent renal loss of sodium with resultant decrease in adrenal cortical activity. Our findings indicate that in the normal subject, the conserva-

tion of body sodium by variation of renal excretion of sodium is the result of increased adrenal cortical activity in response to low sodium intake and decreased adrenal cortical activity when large amounts of sodium are administered.

ACKNOWLEDGMENT

The authors wish to acknowledge gratefully their appreciation to Dr. L. H. Newburgh whose interest and wise guidance made this study possible.

SOME EFFECTS OF VARIATION IN SODIUM INTAKE AND OF DIFFERENT SODIUM SALTS IN NORMAL SUBJECTS¹

By ALEXANDER LEAF, WILLIAM T. COUTER, AND L. H. NEWBURGH

(From the Department of Internal Medicine, The Medical School, University of Michigan, Ann Arbor, Mich.)

(Received for publication February 25, 1949)

In a separate paper (1) we have described effects resulting from variation of sodium intake in normal subjects, which we attribute to changes in adrenal cortical activity. It is the purpose of this paper to describe some additional effects of considerable physiological interest that were observed in the course of that study.

METHODS

Three normal young adults were maintained throughout the study on a constant diet adequate in calories and protein with a very low sodium (about 9 mEq.) and chloride (about 25 mEq.) content. At definite periods 480 mEq. of sodium were administered orally daily either as sodium chloride or as sodium citrate. The analytical methods and diet are described in detail in the previous report (1).

RESULTS

The complete data of this study were presented in a separate paper (1). Only data pertinent to the present discussions will be presented here.

Table I shows the weights of our three normal subjects for the three days before, during and following sodium administration. It is evident that with sodium chloride administration a much more marked gain of weight occurred than with sodium citrate. Each subject was on a maintenance caloric intake so that practically all weight changes occurring over such short periods as these are due to change in body fluid content.

Table II shows the changes in urinary sodium, chloride and potassium excretion that occurred before, during and following each period of sodium administration. No significant changes in fecal sodium, chloride, and potassium were noted and these are not recorded here. It is seen that with administration of sodium chloride there is in each case a parallel increase in both urinary sodium and chloride as would be expected. Following the

sodium citrate administration a similar increase in sodium excretion is noted; however, chloride excretion remains unchanged, or if anything, slightly decreases.

Table II shows further that with the sodium chloride administration no significant increase in potassium excretion occurred except in the case of M. L., whose urine potassium content rose from about 40 mEq. in 24 hours to 88 mEq. the first day of sodium chloride administration. In subjects W. C. and E. W. a significant decrease in potassium excretion occurred after cessation of sodium chloride administration. On the first day of sodium citrate administration, a very definite increase in potassium excretion took place in all subjects. This was followed, after omission of sodium citrate, by a decrease to unusually low levels of potassium excretion.

Table III shows the data we have collected re-

garding glomerular filtration rate and sodium and chloride excretion in these normal subjects. In subject E. W. the glomerular filtration rate is estimated from the 24 hour endogenous creatinine clearance (2, 3). In our other two subjects, glomerular filtration rate was determined by inulin clearances (4). The sodium and chloride excretions were obtained simultaneously with the filtration rates.

DISCUSSION

The discussion is organized about the four points we wish to stress:

I. The importance of fixed anion as well as cation to the accumulation of extracellular fluid.

As is well known, quantitatively the important cation of the extracellular fluids is sodium, and through renal regulation the concentration of sodium in the extracellular fluids is maintained within very narrow limits. Even in disease it is uncommon to find the serum sodium concentration varying more than 20 mEq./L from the normal value of about 140 mEq. Thus, it has come to be generally realized that extracellular fluid volume does not increase without available sodium

(5). This fact has become the central principle in the management of clinical edema by sodium restriction.

Furthermore it is true that the important anion of the extracellular fluid regarded quantitatively is chloride. Little, however, is mentioned regarding the role played by chloride in the accumulation of extracellular fluid. Table I and Figure 1, which show the changes in body weight that occurred with administration of equivalent amounts of sodium first as sodium chloride and then as sodium citrate, clearly indicate that weight gain is much greater following administration of sodium chloride. In short experiments of this type, change in weight is necessarily due almost entirely to changes in body fluid content. Calculation of predicted weight change from increase in chloride space following sodium chloride administration reveals that the weight gain is almost entirely due to increase in extracellular fluid. Figure 1 shows that the serum sodium and chloride concentrations in subject E. W. rose slightly and equally on administration of sodium chloride.

The inability to accumulate much extracellular fluid and gain weight when the same amount of sodium was administered as the citrate salt was

apparently due to the lack of fixed anion, specifically chloride. Since the citrate anion is metabolized in the body it leaves the sodium cation without an accompanying fixed anion. Classical studies have shown that when sodium enters the extracellular fluid compartment without equivalent fixed anion it becomes largely associated with bicarbonate, equivalent for equivalent, keeping the total cation and anion concentrations of the extracellular fluids equal. Such an increase in bicarbonate concentration tends to produce an alkalosis (rise in pH above the normal value 7.35) in the extracellular fluids. The magnitude of this disturbance is diminished by removal of sodium

from the extracellular fluid by renal excretion and by its entry into the intracellular compartment. The extent to which these two regulatory mechanisms failed to prevent a temporary increase in bicarbonate concentration in the extracellular fluid of E. W. is indicated in Figure 1 by the rise in serum sodium from 138.6 to 144.9 mEq. per liter and drop in serum chloride from 97.6 to 95.6 mEq. per liter that occurred with the sodium citrate administration. The serum CO₂ content rose from 30.3 to 37.3 mM per liter. As the low chloride intake had already resulted in very small amounts of chloride in the urine, the kidneys were unable to make fixed anion available in significant amounts

by any further reduction in urine chloride excretion. The slight weight gain that occurred was associated with the small expansion of extracellular fluid volume made permissible by the dilution of the existing chloride content of the extracellular fluid. Thus in the absence of fixed anion, administration of sodium, even in large amounts, does not increase extracellular fluid volume importantly.

II. Dissociation of renal sodium and chloride excretion

Table II clearly shows that when sodium chloride is administered there occurs a parallel increase in urinary excretion of sodium and chloride. With the administration of sodium citrate a similar increase in urinary sodium occurs but the urinary chloride continues to be small or even

FIG. 1. TO SHOW CHANGES IN BODY WEIGHT, SERUM SODIUM AND CHLORIDE CONCENTRATIONS TOGETHER WITH SODIUM (LOWER) AND CHLORIDE (UPPER) BALANCES IN SUBJECT E. W.

Note especially the decreased chloride excretions occurring during the period of sodium citrate administration.

decreases below the base line. This is illustrated in Figure 1 for subject E. W.

In another report (1) we present evidence to support the belief that the renal excretion of sodium in normal human subjects is regulated by adrenal cortical activity. Earlier studies by others of the action of adrenal cortical extracts and adrenal cortical hormones on sodium and chloride balance suggested a similar effect on both sodium and chloride (6-8). Such studies in the past have been conducted under conditions that might be expected to cause parallel changes in sodium and chloride balance, *i.e.*, loss of sodium and chloride in the urine following adrenalectomy and retention of sodium and chloride on administration of adrenal cortical extract or adrenal cortical steroids to adrenalectomized animals. But when a definite need on the part of the body to conserve fixed anion, chiefly chloride, is created because of the presence of a large excess of sodium cation, a complete dissociation in the renal excretion of sodium and chloride is elicited. Our earlier studies (1) indicate that large intakes of sodium, either as the chloride or citrate salts, depress adrenal cortical activity. This would permit the large urinary excretion of sodium that followed the administration of sodium citrate; but accompanying this extensive removal of sodium there is no increased loss of chloride. In fact the urinary values for chloride fell below those of the control period. What it is that causes the kidneys to conserve chloride when excess base is administered, this study does not indicate. It is recognized, however, that such reduction of renal excretion of chloride serves a useful function in conserving fixed anion in the presence of the threat of alkalosis resulting from the sodium citrate administration—another example of the "wisdom" of the body.

III. Displacement of intracellular potassium by sodium

It was noted that each of our subjects showed a prompt and striking increase in urinary potassium excretion during the first 24 hours of sodium citrate administration. By the third day of the sodium citrate period the urinary potassium had dropped to or below the base line (see Table II). No such increase in urinary potassium content occurred with sodium chloride administration ex-

cept possibly for the much less striking increase in subject M. L. Figure 2 shows the theoretical potassium balance calculated from the actual nitrogen balance (grams nitrogen balance $\times 2.7 =$ mEq. theoretical potassium balance on the basis of changes in body protoplasm) and indicates that this potassium excretion was not the result of increased catabolism of tissues. Figure 2 also clearly shows that this marked potassium diuresis coincided with the markedly positive balance of sodium unaccompanied by fixed anion that resulted from the sodium citrate administration.

To learn more about the association of positive sodium and negative potassium balance the calculations shown in Table IV were made according to the method of Darrow (9) for the periods of sodium administration in each subject. The extracellular fluid volume was estimated as 20%² of the body weight on the morning of the first day of sodium administration. It is seen from Table IV that in each case with sodium citrate administration there is a positive intracellular sodium balance, definite in E. W. (222 mEq.) and M. L. (178 mEq.) and perhaps equivocal in subject W. C. (83 mEq.). This is associated with a negative

² Recent evidence by inulin space determinations (20) indicates that the extracellular fluid volume may be less than this per cent. Our subjects also had some shrinkage of extracellular volume as a result of the preceding restriction of sodium and chloride intake. However, the value taken for the initial extracellular fluid volume in these calculations, within reasonable limits, only insignificantly affects the results.

TABLE IV
*Changes in intracellular sodium and potassium balances that occurred during the three-day periods of sodium chloride and sodium citrate administration**

* The complete data from which these calculated values were derived are presented in our preceding paper (1).

FIG. 2. THE ACTUAL AND THEORETICAL POTASSIUM BALANCES (UPPER) AND SODIUM AND CHLORIDE BALANCES (LOWER) IN SUBJECT E. W.

Note that the sodium and chloride balances change together except during and following the period of sodium citrate administration. The factor 2.7 was used to convert grams of observed nitrogen balance to milli-equivalents of "theoretical potassium balance." The values plotted are the difference between intake and urine plus fecal excretions. Note the large negative potassium balance during the first day of sodium citrate administration.

intracellular potassium balance of -110 , -79 , and -133 mEq. respectively for the three-day period.

This method of calculation originated by Darrow is based on the assumption that nearly all of the chloride of the body is restricted to the extracellular fluid compartment. The significant positive figures for "intracellular sodium balance" (or sodium that cannot be accounted for in the extracellular fluids of the body) clearly indicate that sodium has entered some part of the body unaccompanied by chloride. The coincident strongly negative potassium balance is good evidence that this sodium entered the intracellular compartment without chloride, displacing potassium, in so doing. We make no attempt to quantitate the intracellular sodium gain with the potassium loss, as extraneous factors, such as increase in tonicity of the extracellular fluid that occurred with the sodium administration and which might require changes in the total cation concentration within the cells, invalidate such attempts.

Administration of the sodium cation with fixed anion as sodium chloride resulted in no such gain in intracellular sodium. The total gain in body sodium was associated with nearly an equivalent gain of chloride. The sodium gain was accounted for by the increase in chloride space—expanded extracellular fluid volume. There was no occasion for sodium to pass into the cells. Hence no displacement of potassium occurred.

These findings, namely, displacement of intracellular potassium on administration of sodium citrate,³ strongly support the excellent studies of Darrow (8, 10-13) that the intracellular sodium plays a role in the defense of the normal extracellular pH.

The data presented in the preceding publication (1) offer an explanation of the lag in excretion of sodium on changing from low to high intake

³ One may anticipate exactly similar effects from sodium bicarbonate, acetate, lactate or other sodium salts having an associated anion that will be metabolized to bicarbonate in the body.

of sodium. Namely that the sharp restriction of sodium just before the administration of sodium citrate, resulted in maximal reabsorption of sodium in response to augmented adrenal cortical activity. This effect in decreasing amounts was continued for several days after the subjects had begun to take the sodium citrate. Thereafter, the adrenal drive relaxed and the large intake of sodium was accompanied by a plentiful excretion of sodium. During this lag in renal adjustment, the sodium cation passed into the cells of the body from the extracellular fluids, without accompanying fixed anion. This reduced the "available base" (or CO_2 content) of the extracellular fluids, and hence the extent of alkalosis that would have otherwise been produced by the sodium citrate administration. Had this shift of sodium into the cells failed to occur in subjects E. W. and M. L. an increase in the extracellular CO_2 content of 15 and 12 mM per liter, respectively, might have occurred with a resultant severe alkalosis.

The renal excretion of the potassium displaced from the cells was not impeded by the augmented adrenal cortical activity as was the sodium, since the potassium appeared in the urine. Desoxycorticosterone, the adrenal cortical salt-and-water-hormone par excellence, facilitates renal excretion of potassium while decreasing renal excretion of sodium (14). Hence the adrenal cortical activity during the lag in adjustment to the high sodium intake, though it prevented renal excretion of sodium, perhaps facilitated renal excretion of potassium. In subject E. W. the urine collection during the first 24 hours of sodium citrate administration was divided so that the urine passed during the first six hours of sodium citrate administration was collected separately and on analysis was found to contain only 1.4 mEq. of sodium (out of a total excretion of 215 mEq. for that 24 hour period) while it contained more than one-fourth of the total large potassium excretion of that day.

The negative intracellular sodium balance that followed the sodium chloride administration in subject E. W. is of sufficient magnitude to be interesting. The administration of large amounts of sodium chloride, which is "acid-producing" in that it contains equivalents of sodium and chloride (whereas the extracellular fluids normally contain sodium to chloride in the ratio of 1.4 to 1), apparently caused a transfer of intracellular so-

dium to the extracellular fluids which would serve to help combat this effect of sodium chloride administration. Such a mechanism assisting in the prevention of acidosis has also been described by Darrow (11, 15).

It is realized that the type of calculation made above would include any extrarenal or extrafecal sodium loss from the body as a gain in "intracellular sodium." This possibility reduces itself to losses of sodium through the skin. The studies of Freyberg and Grant (16) of the insensible losses of sodium from the skin of normal adult subjects show that the daily sodium loss is less than 10 mEq. Hence in our normal subjects who avoided exertion and sweating, a cumulative loss of sodium through the skin over the three-day periods of about 30 mEq. would scarcely affect the positive balances recorded.

IV. *Glomerular filtration, tubular reabsorption and the excretion of sodium*

There has been considerable discussion in the current literature regarding the possible roles played by change in glomerular filtration rate and tubular reabsorption of sodium in the formation of edema (17-19). Because our studies involved very low and very high rates of sodium and chloride excretion resulting from the marked variations in sodium intake, observations were made to determine, if possible, how glomerular filtration and tubular reabsorption of sodium affected the excretion of sodium by normal subjects. Table III shows the simultaneous 24 hour endogenous creatinine clearance taken as a measure of glomerular filtration rate (2, 3) and the simultaneous 24 hour urine sodium and chloride content. Simultaneous inulin clearances and sodium excretions for subjects M. L. and W. C. are also recorded.

It is obvious from a brief examination of these data that there is no correlation between glomerular filtration rate and renal excretion of sodium or chloride. Following the sodium chloride administration an increase in glomerular filtration rate is associated with an increased rate of excretion of sodium. However, no such increased rate is seen following the sodium citrate administration in spite of an equally large increase in the rate of sodium excretion. In another paper (1) we have suggested that the increased glomerular filtration rate

following sodium chloride administration is a non-specific response secondary to the resulting increased vascular volume. One certainly is not justified in interpreting it as a specific adjustment of the kidney for the purpose of increasing sodium excretion as has been postulated recently (18). Our findings in normal subjects are similar to those of Briggs *et al.* (19) who found no relation between glomerular filtration rates and sodium excretion in patients with congestive heart failure.

In what has just been said, mention of the serum sodium and chloride concentrations at the time of these clearance studies has been purposely avoided. Mokotoff *et al.* (18) have claimed that the tubular reabsorption of sodium is constant per unit of glomerular filtrate volume ("13.3 mM per 100 cc. of glomerular filtrate") and therefore varies directly with the glomerular filtration rate. These workers subtracted the sodium excreted in the urine from the product of the glomerular filtration rate and the serum sodium to obtain the rate of tubular reabsorption. As the quantity of sodium filtered is in nearly all cases tremendous in comparison with the quantity excreted such calculations are questionable. With a glomerular filtration rate of 160 liters in 24 hours and serum sodium of 140 mEq. per liter our subject E. W. was presenting approximately 22,400 mEq. of sodium to his renal tubules while the 24 hour urinary sodium excretion varied between 0.6 and 500 mEq. depending on the sodium intake. Thus as some 97% of the filtered sodium was always reabsorbed, the relatively large shift in urinary sodium must have occurred as a result of variations within this remaining 3% of the filtered sodium. In edematous cardiac and nephritic patients the glomerular filtration rate, though somewhat reduced (17-19), remains sufficiently large to still make the quantity of sodium excreted only a very small percentage of that filtered. Accordingly, the answer to the whole problem of the manner in which renal function is altered in certain cardiac and nephritic subjects making them unable to rid themselves of the usual daily sodium intake is hidden in the manner in which this very small fraction of the total filtered sodium is handled. However, methods such as the mannitol clearance with its unavoidable error of about 10% are much too crude to demonstrate these fine changes. One cannot

detect changes of 3% in a function by using a measuring stick with a 10% error.

CONCLUSIONS

Sodium as the chloride and as the citrate salts was administered to normal subjects maintained on very low sodium and chloride diets. The effects on body weight, sodium, potassium, chloride and nitrogen balances were recorded. Simultaneous glomerular filtration rates and urinary excretions of sodium and chloride were obtained.

The gain in body weight with sodium chloride was strikingly greater than with sodium citrate. Ingestion of sodium as chloride caused parallel increases in urinary excretion of sodium and chloride, whereas sodium as citrate resulted in a similar increase in urinary sodium but the urinary chloride did not increase. Since in the previous paper (1) it was concluded that the desoxycorticosterone-like hormone activity of the adrenal cortex is depressed by sodium administration, this dissociation of sodium and chloride excretion demonstrates that some other factor causes renal conservation of chloride.

When sodium was administered as the citrate salt, a large increase in body sodium occurred accompanied by a large diuresis of potassium. Appropriate calculations indicate that significant amounts of sodium entered the cells, displacing large amounts of potassium.

The quantities of sodium appearing in the urine from 0.6 to 4.77 mEq. bore no relationship to the simultaneous volumes of glomerular filtrate. The sodium present in the urine is 3% or less of the sodium delivered to the tubules in the glomerular filtrate. Accordingly the relatively small variation in the amount of sodium not reabsorbed determines whether body sodium will be increased or decreased. Since the error inherent in the present methods is greater than the function to be measured, the exact role of filtration rate and tubular reabsorption in the excretion of sodium cannot at the present time be defined.

ACKNOWLEDGMENTS

The authors wish especially to thank Drs. Augusto Camara and Vivian Iob, Miss Barbara Stone, and Mrs. Clara Noble for their invaluable technical assistance during this study.

FURTHER STUDIES WITH THE SALT TOLERANCE TEST IN NORMAL INDIVIDUALS AND IN PATIENTS WITH ADRENAL CORTICAL HYPERFUNCTION

BY L. J. SOFFER, J. L. GABRILOVE, AND M. D. JACOBS

*(From the Endocrine Section of the Medical Services and the Chemical Laboratories of
The Mount Sinai Hospital, New York City)*

(Received for publication November 26, 1948)

In a previous paper (1) we reported on the utilization of intravenously injected salt before and after the injection of desoxycorticosterone acetate in normal individuals and in patients with Cushing's syndrome. It was pointed out that the injection of this steroid in normal individuals resulted in a decrease in the urinary excretion of sodium and chloride ions as compared to the control values. This is the expected and orthodox effect. On the other hand, the injection of this compound in patients with Cushing's syndrome under the circumstances of our test resulted in an increase in the urinary excretion of sodium and chloride.

Since the publication of the original paper several reports have appeared describing a similar phenomenon occurring under a variety of conditions. Reifenstein (2) has noted a paradoxical salt loss in patients with Cushing's syndrome treated with testosterone. Kriss and Futcher (3) have observed that in two of three patients with Cushing's syndrome, the rate of urinary excretion of sodium, chloride, and water following the rapid intravenous administration of 400 c.c. of 5% saline exceeded that observed in similarly treated control subjects. In the patients with Cushing's syndrome the increased excretion of the ions and water was accompanied by a reduction in renal tubular reabsorption of these substances, as compared to the controls. In addition, these authors report the instances of two obese females with arterial hypertension in whom the salt tolerance test, employing our technique, was positive at the time of menstruation and negative in the same patients during the intermenstrual period. They suggest that during the menstrual cycle there is a temporary preponderance of adrenocortical influence. In one patient with Cushing's syndrome the salt tolerance test resulted in a normal salt retaining response, despite the fact

that the patient exhibited salt diuresis during the clearance study performed five days previously. More recently, Forsham and his coworkers (4) confirmed the paradoxical salt loss following the injection of desoxycorticosterone acetate in patients with Cushing's syndrome. They suggested that the mechanism of this phenomenon was perhaps dependent upon a competitive renal inhibition of desoxycorticosterone as against some other non-salt retaining adrenal cortical fractions.

The mechanism of this paradoxical effect is obscure. We have speculated that it is at least theoretically possible that in some patients with adrenal cortical hyperfunction excessive amounts of salt-retaining fractions, manufactured by the increased activity of the adrenal cortex or injected from an exogenous source, are converted into substances lacking salt-retaining effects. The basic structural similarity between those adrenal cortical steroids exercising a salt retaining effect and those lacking it would suggest that the conversion of one into another is perhaps chemically feasible.

METHOD

The method of study employed is that described previously (1). "All tests were conducted according to the following standard routine: The patients were permitted no food throughout the period of observation and no fluid after 7 P.M. the night before. At 6 A.M. on the morning of the studies the patient was asked to void and the urine was discarded. He was then given 500 c.c. of water to drink at one time, and all of the urine voided was collected over a three-hour period to 9 A.M., carefully labeled and set aside. At 9 A.M., 200 c.c. of 5% saline (10 grams of salt) was injected intravenously and the urine voided during the next three hours, to 12 M., was similarly collected and labeled. Two days later the same procedure was repeated, but, in addition, the patient received 10 mgm. of desoxycorticosterone acetate intramuscularly the previous evening at 10 P.M. The urine volume of each period was carefully measured and sodium and chloride determinations were made on each specimen. Sodium was determined according to the method

of Butler and Tuthill (5), and chlorides according to the method of Harvey (6). The total urinary sodium and chloride ions excreted during the 6 A.M. to 9 A.M. period were subtracted from those excreted between 9 A.M. and 12 M. (period after the intravenous injection). The difference represents the excess over the basal excretion of these ions. This figure in milliequivalents, divided by 171 (*i.e.*, milliequivalents in 10 grams of sodium chloride) yields the fraction of the injected ions excreted (Na_e and Cl_e). The comparison of the results obtained during the control period and that after the injection of desoxycorticosterone acetate shows the percentage of increased retention resulting from the use of the hormone."

Twenty-two normal controls and ten patients with Cushing's syndrome were studied in the present series. The diagnosis of Cushing's syndrome in every instance of this group was established by the presence of a classical clinical picture plus the demonstration, by perirenal insufflation or surgical exploration or both, of an adrenal tumor or bilateral adrenal enlargement. Patients with Cushing's syndrome need manifest no overt gross or histological adrenal cortical abnormalities. For purposes of clarity and definition, however, we have limited our present study to those patients who manifested the usual typical clinical picture and anatomical evidence of adrenal disease. Finally, there are probably many abortive forms of either transient or permanent adrenal cortical hyper-

function in which the clinical picture is ill defined, more subtle, and less complete. The response of such patients to the salt tolerance test will await further study.

RESULTS

In the table are presented the results obtained in the normal individuals and in the 15 patients with Cushing's syndrome. Five of these latter patients were discussed in our previous report (1). In one of the present control series there occurred a diuresis of chloride and sodium following the administration of desoxycorticosterone acetate. In three others there was a minimal diuresis of one or the other of these two electrolytes, but a retention of the other electrolyte.

In ten of the 15 patients with Cushing's syndrome there occurred a diuresis of sodium and chloride following the administration of desoxycorticosterone acetate under the conditions of our test. Five patients failed to show the characteristic response. Of this group of five individuals, one showed a minimal diuresis of sodium but a considerable retention of chloride. Two of the remaining four patients had received intensive X-ray therapy to the hypophysis prior to the performance of the test. In one of these two patients the salt tolerance test was performed both before and after X-ray therapy to the pituitary. Before irradiation there occurred a marked diuresis of sodium and chloride following the administration of the compound, while the repetition of the test after conclusion of X-ray therapy resulted in a retention of sodium and a reduction in the chloride diuresis.

Serum sodium determinations were made in nine of the patients with Cushing's syndrome. Three of this group showed a considerable elevation of the serum sodium, while in the remaining six instances the blood electrolyte values were well within the normal range. One of the latter group and all three of the former showed a retention of sodium or chloride, or both, following the injection of the desoxycorticosterone acetate.

SUMMARY

1. The salt tolerance test was performed on 22 normal individuals and on 15 patients with adrenal cortical hyperfunction.
2. In one of the control series there occurred

a diuresis of sodium and chloride following the administration of desoxycorticosterone acetate under the conditions of our test. In three others there was a minimal diuresis of one or the other of these two electrolytes, but a retention of the other electrolyte.

3. In ten of the 15 patients with adrenal cortical hyperfunction there occurred a diuresis of sodium and chloride following the administration of the hormone.

4. Two of the five patients who failed to show the characteristic response had received intensive X-ray therapy to the pituitary prior to the performance of the test. In one of these patients the test was performed both before and after X-ray treatment. Prior to X-ray therapy the administration of desoxycorticosterone acetate resulted in a diuresis of sodium and chloride, while after treatment there occurred a retention of sodium and a reduction in the degree of chloride diuresis.

5. Blood sodium determinations were made in nine patients with adrenal cortical hyperfunction. In three there occurred a considerable elevation of this electrolyte, while in the remaining six instances the serum sodium was well within the normal range.

6. All three of the former group and one of the latter showed a retention of sodium or chloride or both.

THE ACTION OF STREPTOCOCCAL DESOXYRIBOSE NUCLEASE (STREPTODORNASE),¹ *IN VITRO* AND ON PURULENT PLEURAL EXUDATIONS OF PATIENTS²

By SOL SHERRY, ALAN JOHNSON, AND WILLIAM S. TILLET

(From the Department of Medicine of the New York University College of Medicine and the Third Medical Division of Bellevue Hospital, New York City)

(Received for publication April 11, 1949)

In previous reports it has been demonstrated that desoxyribose nucleoprotein is a significant constituent of the solid sediment of purulent exudates (1), and that hemolytic streptococci elaborate, during their growth in broth cultures, a desoxyribose nuclease (streptodornase) in considerable quantities (2). The latter finding was also described independently and concomitantly by McCarty (3).

In a more recent report (4) results have been described which were obtained when partially purified streptococcal concentrates, containing both streptokinase and streptodornase were injected into the pleural cavity of patients suffering from various types of diseases causing fibrinous, purulent, and sanguinous exudations.

The concentrates employed³ were prepared according to methods developed and described by Christensen (5). Since they contained both the fibrinolytic principle, streptokinase, and the pus-liquefying enzyme, streptodornase, it was possible to demonstrate that two enzymatic systems were operative when introduced locally within the areas of disease. Fibrin and fibrinogen were predominant in cases of uninfected loculated hemothorax; desoxyribose nucleoprotein was most conspicuous in cases with thick coarse purulent exudates; in other cases both substrates were present in varying amounts depending on the nature of the underlying disease.

With respect to the streptodornase activity, the earlier reports (1, 4) described the depolymerization of desoxyribose nucleoprotein and desoxyribose nucleic acid, and also demonstrated de-

creases in the amount of the solid sediment of purulent exudates in association with marked drops in the viscosity of the same specimens following intrapleural injections of the streptococcal concentrates.

It is the purpose of this article to describe in detail the biochemical changes induced by the action of streptodornase in association with the characteristic physical changes that have attended depolymerization, and, in addition, the histological and cytological changes that have been made evident by the use of microscopic preparations serially stained by the Feulgen method (6).

The data to be presented were derived from:

1. Determinations of the action of streptodornase on purified desoxyribose nucleic acid derived from calf thymus.
2. Observations of the action on purulent exudates produced, *in vivo*, following the intrapleural injection of streptococcal concentrates containing streptodornase; the effects, *in vivo*, have also been paralleled by comparable experiments conducted *in vitro*, by incubating streptodornase with specimens of purulent exudation derived from patients.

MATERIALS AND METHODS

Streptodornase. This enzyme was contained in the partially purified streptococcal concentrates that have been used throughout these studies. The concentrates also contained streptokinase in measurable quantities. However, the effects to be described in this article are limited to those caused by the nuclease. A unit of streptodornase has been arbitrarily defined as the amount that will cause a drop of one viscosity unit in 10 minutes at 37° C in an enzyme substrate mixture consisting of 2.5 cc. of desoxyribose nucleic acid and 0.1 cc. enzyme solution. The substrate consisted of 0.15–0.2% solution of thymus desoxyribose nucleic acid in M/40 barbital buffer and 0.003 M Mg⁺⁺ at pH 7.4. The substrate had an initial viscosity relative to water of 3–5 units.

The amounts of the enzyme employed will be given in individual protocols.

¹ The word "Streptodornase" has been employed in this article as an abbreviation of streptococcal desoxyribose nuclease.

² This study was supported by a grant from the National Institutes of Health, United States Public Health Service.

³ A considerable amount of the preparations was supplied by Lederle and Co.

Deoxyribose nucleic acid. This was prepared from calf thymus by the method of Mirsky and Pollister (7). A 0.15–0.20% solution in M/40 barbital buffer was heated at 56° C for two hours, to destroy any residual depolymerase activity, before its use as a substrate.

Viscosity. Viscosity measurements were done in a constant temperature bath at $37 \pm 0.2^\circ$ C. For purified deoxyribose nucleic acid solutions or thin exudates, Ostwald viscosimeters with a flow time of 10–15 seconds at 37° C were employed. For thick exudates an LV Model Brookfield viscometer was employed. Results are expressed in units of viscosity $\times H_2O$.

pH. pH was determined by glass electrode using a Beckmann pH meter.

Sediment. The per cent sediment was determined by filling Wintrobe tubes with exudate and spinning at 2500 RPM for one hour.

Phosphorus. Total acid soluble phosphorus was determined by a modification of the method of Fiske and SubbaRow (8) on digested 8% trichloroacetic acid filtrates. Inorganic phosphorus was determined by a modification of the method of Fiske and SubbaRow (8) on 8% trichloroacetic acid filtrates. Organic acid soluble phosphorus was obtained by subtracting the inorganic P from the total acid soluble P.

Acid soluble nitrogen. Determined on 8% trichloroacetic acid filtrates by micro Kjeldahl and nesslerization.

Ammonia. Determined by method of Van Slyke and Cullen (9).

Uric acid. Determined on 1% tungstic acid filtrates by the method of Folin (10).

Absorption at 2600 Å. Determined on trichloroacetic acid filtrates in a Beckmann Spectrophotometer.

Feulgen stain. An adaptation of Rafalko (11) and Stowell's (12) modification of the method originally described by Feulgen (6) has been regularly employed.

Solutions

1. *Lcuco-fuchsin reagent.* 0.5 Gm. basic fuchsin suspended in 100 cc. boiling distilled water. Shake. Cool to 50° C. Filter. Decolorize by slowly bubbling SO_2 through the solution for one to two hours. Store in dark for 24 hours. Add 0.25 Gm. activated charcoal (preferably norit). Shake for one minute and filter rapidly through coarse filter paper. Store in icebox in dark bottle.
2. *1N HCl solution.*
3. *Sulfurous acid solution.* Bubble SO_2 through 1 liter of distilled water for three to four hours in the cold. Store in icebox in dark bottle.
4. *Fast Green F.C.F. solution*—0.02% alcoholic solution.

Technique⁴

1. Thick and thin smears of exudate are made and air dried.

⁴ All procedures are carried out at room temperature unless otherwise specified.

FIG. 1. THE EFFECT OF VARYING AMOUNTS OF STREPTODORNASE CONCENTRATE ON THE DEPOLYMERIZATION OF PURIFIED DEOXYRIBOSE NUCLEIC ACID

2. Immerse in 1N HCl for one minute.
3. Immerse in 1N HCl for 15 minutes at 56° C.
4. Rinse in distilled water.
5. Rinse in sulfurous acid solution.
6. Immerse in leuco-fuchsin solution for two hours.
7. Rinse in three successive baths of sulfurous acid solution for one minute each.
8. Immerse in tap water for five minutes and then rinse with distilled water.
9. Immerse in Fast Green solution for 20-30 seconds.
10. Rinse in distilled water, and air dry.

RESULTS

1. The action of streptodornase on purified desoxyribose nucleic acid (calf thymus).

In Figure 1 the depolymerase activity of 1 to 5 gamma of a streptodornase concentrate in 0.1 cc. was tested with 2.5 cc. of a 0.15% solution of desoxyribose nucleic acid in M/40 barbital buffer containing 0.003 M of Mg^{++} at pH 7.4. The tests were conducted for periods of ten minutes in a water bath at 37°C. From the data it may be noted that a linear relationship between concentration of enzyme and depolymerase activity was demonstrable.

In Figure 2 the effect of temperature on the depolymerase activity of the streptococcal concentrates is illustrated.

For the experiment on thermal effects, 0.1 cc. of a 1:1000 dilution of a 5% crude streptococcal concentrate, and containing approximately 1.4

units of streptodornase was added to 2.5 cc. of a 0.2% solution of desoxyribose nucleic acid in M/40 barbital buffer (pH 7.4) containing 0.003 M of Mg^{++} . Measurements of viscosity were made over periods of ten minutes following mixture of enzyme and substrate.

As may be noted from Figure 2 the rate of depolymerization progressively increased with rising changes in temperature reaching a maximum at 45° C. Above 45° C the rate of enzyme inactivation exceeded the increased velocity of reaction. The activity of the enzyme rapidly fell off as the thermal death point of 56° C was approached. Temperature inactivation of the enzyme appeared to begin above 30° C.

In Figure 3 the relation of pH to streptodornase activity is demonstrated.

To a 0.2% solution of desoxyribose nucleic acid in M/40 sodium barbital containing 0.003 M of Mg^{++} , 3% acetic acid was added in different amounts in order to obtain solutions of substrate varying in pH from 5.2 to 9.0. 0.1 cc. of a 1:1000 dilution of a 5% preparation of concentrate and containing 1.8 units of streptodornase was added. Measurements of viscosity were made over periods of ten minutes in a water bath at 37° C following the mixture of enzyme and substrate. The final pH was checked before and at the end of each experiment.

As may be noted from the data in Figure 3, activity was greatest between pH 7.0 and 8.5.

FIG. 2. THE EFFECT OF TEMPERATURE ON THE DEPOLYMERASE ACTIVITY OF STREPTODORNASE

FIG. 3. THE EFFECT OF pH ON THE DEPOLYMERIZATION OF PURIFIED DESOXY-RIBOSE NUCLEIC ACID BY STREPTODORNASE

In Figure 4, the results of an experiment are summarized that was conducted for the purpose of determining whether acid soluble phosphorus and acid soluble nitrogen were liberated by the action of streptodornase.

0.2 cc. of a streptococcal concentrate containing 180 units of streptodornase per cc. was incubated at 37° C with 67 cc. of a 0.2% solution of purified desoxyribose nucleic acid (calf thymus) containing 0.003 M of Mg^{++} in M/40 barbital buffer at pH 7.4.

From the findings recorded in Figure 4 it may be seen that analyses of trichloroacetic acid filtrates revealed a progressive liberation of organic acid soluble P and acid soluble N and that the activity continued after depolymerization, as determined by viscosity measurements, was completed. Since no significant increase in inorganic P was noted, the rise in total acid soluble P may be interpreted as being entirely dependent on an increase in phosphate esters.

No evidence of deamination was observed. These findings, coupled with the observation of marked increases in the extinction coefficient at 2600 Å of trichloroacetic acid filtrates of desoxyribose nucleic acid incubated with streptodornase, indicate a liberation of acid soluble nucleotides.

A search for inhibitors has been made using a wide variety of reagents that might be pertinent to

the broad problems of this study including the possible significance of inactivation in relation to the effective treatment of patients.

The following substances were found to have no effect on the depolymerase activity of streptodornase: salicylate, gentisate, ascorbate, thiourea, paraminobenzoic acid, parachlorophenol, oxalate, colchicine, and penicillin. In conducting the above experiments 0.1 cc. solution of the test reagents was mixed with the nucleic acid substrate. 0.1 cc. of streptodornase solution containing 1 unit of enzyme was then added and the rate of depolymerization over a ten minute interval observed. The quantities of each reagent employed were estimated as being of sufficient concentration to give an indication of an inhibitory effect if such were present. Since no evidence of inhibition has been found, the observations have not been extended beyond the preliminary stages.

Definite evidence of an inhibitory effect has, however, been noted in the use of citrate and heparin.

The results briefly stated are shown in Table I.

2. The action of streptodornase on the purulent exudates of patients, *in vivo* and *in vitro*

Nine patients with empyema have been studied. The diseases giving rise to the empyema were caused by tuberculosis in four instances, anaerobic

FIG. 4. THE EFFECT OF STREPTODORNASE ON THE DEPOLYMERIZATION AND LIBERATION OF ACID SOLUBLE NITROGEN AND PHOSPHORUS FROM PURIFIED DESOXYRIBOSE NUCLEIC ACID

streptococcus in two cases, pneumococcus pneumonia with sterile empyema in two cases, and infection with *B. pyocyaneus* in one case.

In the study of each case a sample of pleural exudate was removed for analyses prior to the injection. The streptococcal concentrates in amounts of fluid varying from 2 to 10 cc. and containing from 5000 to 50,000 units of streptodornase were introduced into the pleural site of the infection. Subsequent specimens were removed by

thoracentesis during periods of one or more hours in the first day and then usually at daily intervals thereafter for the duration of the observations.

The required dosage of streptodornase in relation to the type and amount of pus present in each case has not yet been determined on an exact quantitative basis. However, the doses employed, usually averaging 20,000 units per dose, have regularly proved effective as evidenced by the definitive changes to be described.

It may be noted at this point that no serious untoward effects occurred in any of the patients. The reactions were limited to pyrogenic ones of a transient nature together with febrile malaise such as that previously described (4). A report of the therapeutic effects of the injections together with the clinical details of the course of the patients is now in preparation.

In six cases of empyema measurements were made of the liberation of organic acid soluble P at the site of the pleural exudation following the local introduction of the streptococcal concentrates containing streptodornase.

Determinations of acid soluble P and N were made on the supernatant portion of centrifuged

TABLE I
Inhibition of streptodornase depolymerase activity by various reagents

Substance tested	Amount in test mgms.	Inhibition %

samples of exudate removed at hourly intervals. From the data in Figure 5 it may be seen that the peak of the rise in liberated P was reached one to four hours after the injection. The values then returned to the pre-injection level during the next 24 hours.

The liberation of acid soluble N was also evident coincidental with the rise in P. The acid filtrates of the supernatant specimens showed marked increases in absorption at 2600 Å. Further breakdown to inorganic P or uric acid was not demonstrable, as shown in Figure 6.

Experiments comparable to those just described have been conducted, *in vitro*, by incubating mixtures of streptodornase and pus, and making determinations of acid soluble P and N liberated into the supernatant fluid. The results of such a study

FIG. 5. THE LIBERATION OF ORGANIC ACID SOLUBLE PHOSPHORUS INTO THE SUPERNATANT OF PLEURAL EXUDATES AT VARYING INTERVALS FOLLOWING THE LOCAL INTRODUCTION OF STREPTODORNASE INTO THE SITE OF DISEASE IN SIX PATIENTS WITH EMPYEMA

FIG. 6. THE CONCENTRATION OF URIC ACID AND INORGANIC PHOSPHORUS OF THE SUPERNATANT OF PLEURAL EXUDATES AT VARYING INTERVALS FOLLOWING THE LOCAL INTRODUCTION OF STREPTODORNASE INTO THE SITE OF DISEASE IN PATIENTS WITH EMPYEMA

are recorded in Table II. The purulent exudate was obtained from a case of penicillin treated pneumococcus Type II pneumonia who developed a sterile empyema. The pH of the fluid was 6.5. The sample of pus was divided into three aliquots. One aliquot served as control. A second aliquot was incubated with a streptococcal concentrate previously heated at 56° C for one and one-half hours to destroy the desoxyribonuclease present. This concentrate still contained considerable streptokinase. The third aliquot was incubated with the unheated streptococcal concentrate containing both streptokinase and desoxyribonuclease.

The control exudate, and the exudate mixed with concentrate free of streptodornase, liberated acid soluble N and P into the supernatant at about the same rate. The concentrate containing strepto-

dornase produced a striking progressive liberation of organic acid soluble P and acid soluble N into the supernatant. The liberation of inorganic P was at the same rate in all three instances.

The above data point to the fact that since no liberation of inorganic P or uric acid was detectable in the supernatant portions of the exudates,

either *in vivo* or *in vitro*, the breakdown of the nucleoprotein of the exudates probably did not proceed further than the nucleotide stage.

A readily obvious physical change caused by the action of streptodornase on the intrapleural purulent exudates is the transformation of the viscid, thick, coarsely granular material to a thin, milky type of fluid. Photographs contained in previous articles (2, 4) demonstrate the extent of the visible change.

Quantitative estimations of the physical changes have been made by determining in the serial samples of exudate derived from the patients the decreases in both the per cent of sediment and viscosity in association with the biochemical changes described above.

Figure 7 demonstrates the effect of the injection on the viscosity of exudates in nine patients.

The range of fall was from 2–2400 viscosity units. Where the initial viscosities were highest because of large amounts of extracellular desoxyribose nucleoprotein, the effect was most striking. This correlation will be demonstrated in the subsequent description of the findings obtained by the use of Feulgen stained preparation.

The range of the per cent fall in one hour in the amount of sediment following injection in nine patients is shown in Figure 8. The observations were made by centrifuging aliquot parts of the serial samples of exudates at approximately 2500 revolutions per minute for 60 minutes.

The results are again closely correlated with

FIG. 7. THE EFFECT OF STREPTODORNASE, INTRAPLEURALLY INJECTED, ON THE VISCOSITY OF THE PLEURAL EXUDATES IN NINE CASES OF EMPYEMA

One patient was injected twice.

both the changes in viscosity and the microscopic demonstration of the lysis of extracellular desoxyribose nucleoprotein.

By the Feulgen method of staining, the presence of desoxyribose nucleoprotein has been identified microscopically as being present extracellularly in considerable abundance. Morphologically it appears, as has been previously described (1), in the form of small granules, fibrous-like strands, and amorphous plaques. Intracellularly, desoxyribose nucleoprotein is noted as a significant part of the nuclei. The extracellular material is obviously derived from destroyed cells, chiefly from the leucocytes of the exudate and to an undetermined degree from local fixed tissue cells. From the cytological studies, leucocytes in various stages of degeneration have also been noted.

The small granular forms of the desoxyribose nucleoprotein have been found to be characteristic of the freshest exudates, the reticular and amorphous forms to be present in greatest abundance in protracted cases of purulent infection such as tuberculous empyema.

When the streptococcal concentrates containing streptodornase have been introduced intrapleurally

FIG. 8. THE EFFECT OF STREPTODORNASE, INTRAPLEURALLY INJECTED, ON THE PERCENTAGE SEDIMENT OF PLEURAL EXUDATES IN NINE CASES OF EMPYEMA

FIG. 9. FEULGEN STAIN OF PLEURAL EXUDATE ASPIRATED FROM A PATIENT WITH A *B. pyocyaneus* EMPYEMA IMMEDIATELY BEFORE THE LOCAL INJECTION OF STREPTOCOCCAL CONCENTRATE

into patients and stained preparations made of serial samples of the exudate, the rapid and complete disappearance of the extracellular material has been observed. The details of such findings in two patients are given in association with the descriptions of the accompanying photographs which are illustrative of the rapidity and completeness of the disappearance of the extracellular desoxyribose nucleoprotein at the site, *in vivo*, of the exudation.

Figures 9 and 10 depict results obtained in a patient with relatively recent exudation consisting chiefly of granules and fibrous strands. Figures 11-13 illustrate the type of Feulgen staining material in a more protracted case of empyema. In both instances the injection of streptodornase resulted in complete disappearance of the extracellular desoxyribose nucleoprotein, within one hour in the first patient, and within two hours in the second patient.

bose nucleic acid from calf thymus has been found to have the following characteristics:

- a. A linear relationship between enzyme concentration and depolymerase activity.
- b. Temperature inactivation of the enzyme exceeds the thermal enhancement of reaction velocity above 45° C. Temperature inactivation is apparent above 30° C.
- c. Depolymerase activity occurs over a wide pH range, and is greatest between 7.0 and 8.5.
- d. In addition to depolymerization, there is a progressive liberation of acid soluble P and N from the substrate. The liberated P appears entirely in the organic form.
- e. Salicylate, gentisate, ascorbate, thiourea, paraminobenzoic acid, parachlorophenol, oxalate, colchicine, and penicillin had no signifi-

The extracellular matrix has been swept clean of the Feulgen staining material. $\times 882$.

The leucocytes remaining visible in the photographs taken following the lytic action represent to the greatest extent, cells that have not degenerated and are morphologically undamaged by the nuclease. A progressive fall in the percentage of degenerating cells, as determined by the Feulgen stain, was regularly observed for at least 24 hours after the injection of the streptococcal concentrate. As shown in Figure 14 the effect is greater, the larger the percentage of degenerating cells in the exudate prior to the injection of the concentrates.

The effect of streptodornase on motility and other functions of leucocytes will be the subject of a separate communication.

SUMMARY

cant inhibitory effect on depolymerase activity. Citrate and heparin were found to have an inhibitory action.

2. Streptodornase has been found to be operative when introduced locally into the pleural cavity of patients with empyema by effecting the rapid depolymerization of the desoxyribose nucleoprotein that has been found to constitute a considerable proportion of the solid sediment of coarse purulent exudates.

The following physical, chemical, histological, and cytological changes have been described in this article.

- a. Grossly visible changes of the coarse sediment to a thin milky type of fluid.
- b. Striking fall in viscosity.
- c. Striking fall in per cent sediment.
- d. Sharp rise in organic acid soluble phosphorus and acid soluble nitrogen.
- e. No rise in inorganic phosphorus.
- f. No increase in uric acid.
- g. Striking decrease in number of degenerated leucocytes.

h. Rapid disappearance of all extracellular Feulgen staining material. (desoxyribose nucleoprotein).

3. The changes mentioned above were demonstrable in a significant degree within one hour following the injection of streptodornase. Following a single dose, they continued for varying periods of time ranging from several hours to several days, but were self terminating.

STUDIES WITH RADIOACTIVE IODIZED FAT. I. PREPARATION OF RADIOACTIVE FAT WITH OBSERVATIONS ON THE ABSORPTION OF FAT FOLLOWING SUBCUTANEOUS AND INTRAPERITONEAL INJECTION IN DOGS¹

BY ALEXANDER M. RUTENBURG, ARNOLD M. SELIGMAN, AND JACOB FINE

(From the Kirstein Laboratory for Surgical Research, Beth Israel Hospital, and the Department of Surgery, Harvard Medical School, Boston)

(Received for publication March 14, 1949)

INTRODUCTION

The intravenous administration of emulsified fat in concentrations suitable for nutritional purposes is not applicable for clinical use because an emulsion stabilizer free of undesirable effects has not yet been developed. Pending the availability of a satisfactory stabilizer, the possibility of parenteral administration of fat by other routes deserves further exploration. Data reported on the absorption and distribution of fat given subcutaneously, intramuscularly and intraperitoneally to animals (1-6) are equivocal or conflicting largely because of the inadequacy of the quantitative analytical methods used. Fat labelled with a radioactive element can be traced and measured with considerable accuracy. While fat labelled with radioactive carbon (C^{14}) (7) or deuterium (8) is ideal, the measurement in tissue is more difficult than that of fat labelled with radioactive iodine. Although iodized fat is unnatural, its digestion, absorption and metabolic fate after oral and parenteral administration is said to simulate closely that of natural fat (9-15). Since iodine is liberated relatively slowly from iodized fat (16), it should, if radioactive, be useful to follow the absorption and immediate distribution of fat, once it enters the circulation. Accordingly, an emulsion of fat labelled with radioactive iodine was prepared with Dermal 14² in order to determine with reasonable accuracy, (1) the absorption and distribution of fat introduced subcutaneously or intraperitoneally, and (2) the distribution of radioactive fat emulsions introduced intravenously. This communication presents a method for the preparation of radioactive fat, to-

gether with data on the absorption of such fat from the subcutaneous and intraperitoneal spaces, with and without hyaluronidase. In a subsequent paper (16), observations on the distribution and fate of radioactive fat emulsions injected intravenously are presented.

EXPERIMENTAL METHODS

Iodination of soya bean oil

A modification of the method for iodination of vegetable oil with iodine monochloride (17) was used for iodination of soya bean oil with $I^{131}Cl$. By this method only one atom of iodine is incorporated upon halogenation of an ethylenic linkage. By using an excess of oil an average of 0.46 atoms of iodine was incorporated into each molecule of fat.³

Potassium iodide (3.6 gms.) was dissolved in 6.2 cc. of distilled water, to which one to two molecules of carrier-free I^{131} (1 cc.) and 2.4 gms. of potassium iodate were added. Concentrated hydrochloric acid (7.2 cc.) was added slowly with vigorous shaking and stirring. The resulting heavy dark precipitate of $I^{131}Cl$ slowly redissolved. A small amount of iodine vapor appeared in the reaction flask during the procedure. The final solution was clear and orange colored. A highly diluted aliquot was taken for radioactivity measurement.

The $I^{131}Cl$ solution was cooled to 4-5° C. and added in three portions with stirring to a cold solution of 50-55 gms. of soya bean oil in 100 cc. ether. The mixture was mechanically shaken for 60-90 minutes at room temperature. The color of the aqueous solution was discharged during this process. The oil-ether solution was straw yellow. It was washed once with water and twice with 5% sodium sulfite in 0.1 N sodium hydroxide solution. It was then washed with water, dilute hydrochloric acid, and finally several times with distilled water. The combined washings contained 2% of the total radioactivity used in the iodination.

³ Pure refined soya bean oil was supplied by E. F. Drew & Co., Inc., Boston. It contains 33.7% oleic acid, 52.0% linoleic acid, 2.3% linolenic acid and 11.2% palmitic and stearic acids. The molecular weight of this oil is about 876 and each molecule contains approximately 4.3 double bonds.

¹ Aided by a grant from the Patrons of Research, Beth Israel Hospital, Boston.

² A preparation of polyglycerol esters provided through the courtesy of Emulsol Corp., Chicago.

The ether solution was dried with anhydrous sodium sulfate and the ether was removed by distillation under nitrogen at reduced pressure and at a temperature between 40–50° C. The residual oil was pale yellow. No radioactivity due to inorganic iodine could be extracted from the oil with sodium sulfite solution after standing in the dark for ten days. The yield was 56 gms. In several runs 80–90% of the iodine used was incorporated in the fat, as determined both by radioactivity measurements and iodine titration.

A 10% emulsion of radioactive oil in water was made with the aid of "Demal 14" as follows: One part of Demal was dissolved in two parts of oil, water was added and the entire mixture was blended for 10 minutes in a Waring blender and then recirculated in a high pressure homogenizer for 60 minutes. Microscopic examination revealed the larger fat droplets to be approximately 0.5–2.0 micra in diameter.⁴

Radioactivity determination (18, 19)

Either 2 cc. of blood or 1 cc. of plasma was evaporated for 48 hours at 37° C. to dryness in an aluminum cup, 2 cm. in diameter. In experiments in which tissues were analyzed, several onc-gram specimens of liver, spleen, lung, mesenteric fat, omentum, kidney, intestines, and thyroid were removed in thin slices, immediately after death by exsanguination, wiped dry of all excess blood, and rapidly weighed on a torsion balance. They were then spread out in a thin layer in aluminum cups and evaporated for 48 hours at 37° C. to dryness.

A two to four hundredfold dilution of the radioactive oil or emulsion which was used for injection was prepared with non-radioactive oil or emulsion. An aliquot of this solution was evaporated with 2 cc. of blood or 1 cc. of plasma from a normal dog in order to prepare a standard approximating the dry weight of the experimental samples.

Radioactivity measurements were made on a Tracerlab Autoscaler with a Victoreen Geiger tube (bell type with end mica window weighing 3.6 gms./cm.²). The tube and samples were shielded with 1.5 inches of lead. All specimens were at least five times background, unless otherwise indicated.

Radioactivity measurements were calculated for total activity circulating in the blood or plasma in per cent of total activity injected in the form of oil or emulsion. Tissue radioactivity was calculated in terms of radioactivity per whole weighed organ or tissue in per cent of total activity injected. The standards prepared with normal dog blood were used in making these calculations. For the purpose of these calculations the skeletal muscle was assumed to have 30% (20) and the blood volume 10% of the body weight. The hematocrit was taken as 50%.

ANIMAL EXPERIMENTS

Subcutaneous injection of radioactive iodized oil

Ten cc. of radioactive oil were injected into the subcutaneous tissues of the flank in each of two dogs. Just prior to the injection of the oil, one of these dogs was also given 20 mgs. of hyaluronidase⁶ in 25 cc. of saline into the same site. In both dogs the injected tissues were massaged to disperse the injected material.

The rate of absorption of radioactive fat into the circulation was determined by measuring serial blood samples for radioactivity. At no time in the following 48 hours was more than 0.25% of the total radioactivity injected found in the circulating blood (Table I). After four to five days the sites of injection retained virtually all of the oil still unabsorbed.

TABLE I
Radioactivity* circulating in the blood† of dogs after the subcutaneous injection of 10 cc. radioactive iodized soya bean oil

* Radioactivity expressed in per cent of total radioactivity injected.

† Blood volume estimated as 10% of body weight.

Ten cc. per kilogram of body weight of the radioactive fat emulsion were injected subcutaneously into each of four dogs. In three of these dogs 5–10 mgs. of hyaluronidase were injected into the same site just before injection of the emulsion. The tissues were massaged following injection of the emulsion. The results were similar to those with liquid radioactive oil. At no time during the following week was more than 0.5% of the total radioactivity injected found in the circulating blood (Table II). Analysis for radioactivity of the major tissues three to five days after injection

⁶ Hyaluronidase is said to increase the rate of absorption of substances injected subcutaneously (21–24) by virtue of the increased surface area made available by its hydrolytic action on the hyaluronic acid gel of the connective tissues. Hyaluronidase was provided through the courtesy of Schering Corp. The assay of each milligram was 50 turbidity reducing units.

* Radioactivity expressed in per cent of total radioactivity injected.

† Blood volume estimated to be 10% of body weight.

revealed that less than 0.5% of the total radioactivity injected was present in all the tissues combined. The thyroid gland also contained the same low order of radioactivity as other tissues. Only a trace of radioactivity was found in the feces and urine. The injection site contained nearly all of the emulsion. Therefore, neither emulsification nor hyaluronidase improved the absorption of radioactive fat from the subcutaneous tissues.

Intraperitoneal injection of radioactive iodized oil

Ten cc. per kilogram body weight of radioactive fat emulsion were injected intraperitoneally into six dogs. In five of these dogs (Nos. 9, 11-14), 5-10 mgs. of hyaluronidase in 50 cc. of saline were injected intraperitoneally five to 10 minutes prior to the administration of the oil. The results are summarized in Table III.

In Dog 10, which did not receive hyaluronidase, less than 0.5% of the total radioactivity injected was found in the circulating plasma. The same was true in Dogs 11, 12, and 14, which did receive hyaluronidase. Dog 11 was first given the

fat emulsion without hyaluronidase; but six weeks later, he received it again with hyaluronidase. The circulating radioactivity was not increased by the hyaluronidase.

In Dogs 9 and 12, by the 12th day after injection, 8% and 3% respectively of the total radioactivity injected was found in the circulating plasma.

The tissues of Dogs 10, 12, 13 and 14, sacrificed 12-15 days after injection, failed to reveal any radioactivity, except in the peritoneal cavity, which was free of any noticeable reaction to the presence of the fat or hyaluronidase.

DISCUSSION

Our finding of a low order of radioactivity in plasma and tissues, including the thyroid, confirm the view that the subcutaneous route is unsatisfactory for the parenteral administration of fat or fat emulsion. The absorption is too slow and is not noticeably accelerated by hyaluronidase, which does speed up the absorption of water, electrolytes, and plasma (24, 25).

* Radioactivity is expressed in per cent of total radioactivity injected.

† Plasma volume estimated to be 5% of the body weight.

Absorption of fat from the peritoneal cavity is also unsatisfactory. In two of the five dogs which received hyaluronidase, a relatively high level of circulating radioactivity was present from the third day up to the 21st (Dog 9), and the 16th (Dog 12) day respectively following injection of the emulsion. Since injected ionic iodine is rapidly excreted (18), the continuous presence of radioactive iodine in the plasma of these dogs is due either to the continuous slow absorption of the iodized fat or to slow liberation of I^{131} from the iodized fat *in situ*. How much of the circulating radioactivity was ionic iodine cannot be stated. In another publication (16), data are presented showing that 24 hours after intravenous injection of emulsified radioactive fat, only 10% of the radioactivity in plasma is in the form of ionic iodine, while 60% is in the lipid fraction. We did not make this fractional determination in Dogs 9 and 12, but one might postulate a similar distribution in these dogs. A possible relationship between the nutritional state of the animal and the rate of absorption from the peritoneal cavity is suggested, since there was a weight loss of 7–8 lbs. in the course of the experiment in Dogs 9 and 12, whereas Dogs 10, 13, and 14 either maintained or gained weight. Dog 11 showed greater absorption in the second experiment, in which there was a weight loss of 3.5 lbs., than in the first experiment in which there was a weight gain of 2 lbs.

Although virtually all the fat injected intraperitoneally remained there at least 16–17 days, intraperitoneal adhesions did not form in dogs which received hyaluronidase. Since adhesions have been observed from intraperitoneally injected fat without hyaluronidase (5), these observations suggest that this enzyme may be useful to prevent adhesions.

CONCLUSIONS

A method for preparing radioactive iodized oil is described.

Following subcutaneous or intraperitoneal injection of emulsions of this oil, absorption was slow and nearly all of it remained at the site of injection.

Hyaluronidase did not increase the rate of absorption of tagged fat from the subcutaneous or peritoneal space.

STUDIES WITH RADIOACTIVE IODIZED FAT. II. THE TISSUE DISTRIBUTION OF EMULSIFIED FAT FOLLOWING INTRAVENOUS ADMINISTRATION¹

BY ALEXANDER M. RUTENBURG, ARNOLD M. SELIGMAN, AND JACOB FINE

(From the Kirstein Laboratory for Surgical Research, Beth Israel Hospital, and the Department of Surgery, Harvard Medical School, Boston)

(Received for publication March 14, 1949)

The rate of absorption of emulsified fat labelled with radioactive iodine from the subcutaneous tissues and the peritoneal cavity in animals is too slow to serve as a source of current caloric requirements (1). Since parenteral administration to patients for this purpose would require that the fat be given in high concentration intravenously, it is necessary to prepare a stable, non-toxic emulsion. This has not yet been accomplished (2-7). Pending the availability of such an emulsion, it is desirable to study the metabolic fate of fat given intravenously. One of the first steps in such a study is the distribution of the injected fat. Numerous studies of fat, tagged with non-radioactive iodine, given by vein, fail to agree as to its distribution (8-19). The conflicting results are in part due to variations in particle size and to lack of reliable techniques for determining tissue localization and quantitative distribution.

In this communication, we report the quantitative tissue distribution of the radioactivity found after the intravenous injection into dogs and mice of an emulsion of radioactive iodized soya bean oil. The oil was labelled with radioactive iodine by a technique reported in a preceding paper (1). It was then prepared as an emulsion as follows:

Preparation of the emulsion

Radioactive iodized soya bean oil (1) was emulsified in water with the aid of "Demal 14." ² Twenty-five gms. of this detergent were dissolved in 50 gms. of the oil, and the resulting solution was warmed to 80° C. and slowly added to 425 cc. of warm distilled water in a rotating Waring blender. The blending was continued for ten minutes after the oil mixture had been added. The resulting crude emulsion (10%) was then homogenized by recirculation for 60-90 minutes in a two-stage

homogenizer at 3300-3500 lbs. of pressure per square inch. The temperature rose to 70-85° C. The final product appeared blue by reflected light and reddish by transmitted light, an indication of fine particle size (20). On microscopic examination the oil globules ranged from approximately 0.5 to 2.0 micra in diameter. The emulsion was stable at room temperature for one to two weeks. Since sterilization by autoclaving destroyed the emulsion and decreased its pH from 8.0 to 4.3, it was passed through a Seitz filter before use. The emulsion was found apparently non-toxic and well tolerated when given orally and intravenously to mice and dogs.

ANIMAL EXPERIMENTS

Intravenous administration in dogs

Each of eight mongrel dogs (weight range 8-12 kgs.) was given a single slow intravenous injection (1.2-4.2 cc./kg.) of the emulsion. Venous blood samples were drawn at intervals. Two cc. of blood or 1 cc. of plasma was used for radioactivity measurements. Standards consisted of highly diluted aliquots of the emulsion, to which 2 cc. of normal blood or 1 cc. of normal plasma was added. The technique of radioactivity measurement has been described elsewhere (1).

The results, listed in Table I, show that at the end of the first hour following injection about 2% of the total injected radioactivity was circulating in the blood of Dog 8, and about 1% in the plasma of Dogs 8, 20-24. There followed a slow increase, so that some 24 hours later the maximum concentration of circulating radioactivity was reached (some 3% to 7.5% of the total injected radioactivity). This maximum, with some variation, persisted for another 24-48 hours and gradually declined thereafter.

Plasma Fractionation Experiments

The distribution of the circulating radioactivity among the plasma components was examined by fractionation of plasma specimens drawn from several dogs 24-30 hours after injection of the emulsion.

¹ Aided by a grant from the Patrons of Research, Beth Israel Hospital, Boston.

² A blend of di-tri and higher polyglycerols, partially esterified with oleic acid. Supplied by the Emulsol Corp., Chicago, Illinois.

TABLE I

Circulating radioactivity at various intervals after injection of radioactive fat emulsion in dogs*

* Assuming blood volume to be 10% and plasma volume to be 5% of body weight.

The isolated fractions or their aliquots were transferred to aluminum cups (2 cm. in diameter), evaporated to dryness and the radioactivity measured (1). The results were calculated in per cent of the radioactivity of the plasma which was fractionated.

Four types of fractionation experiments were performed as follows:

Experiment 1.—Analysis of lipid fractions of plasma by alcohol-ether extraction

Total lipids and phospholipids were isolated from the plasma according to the method of Bloor (21). The plasma proteins precipitated by the alcohol-ether mixture were also collected. The total protein and phospholipid fractions contained only traces of radioactivity, while the total lipids contained 50-65% of the radioactivity.

Experiment 2.—Analysis of the alcohol-ether extract of plasma

An alcohol-ether (lipoid) extract of plasma was evaporated to dryness and the lipoids in the residue redissolved in hot petroleum ether. The petroleum ether extract contained 60% of the total radioactivity of plasma.

The residue, after lipid extraction, was redissolved in water. An aliquot of this solution showed that it contained 20% of the total radioactivity of whole plasma.

The aqueous solution remaining after extraction with alcohol-ether was acidified with nitric acid. Carrier sodium iodide and a solution of silver nitrate were added in that order. The yellow silver halide precipitate was collected, washed thoroughly with water, acetone and ether. The radioactivity of this precipitate (*i.e.*, ionic iodine) was 9-12% of the total radioactivity (standard prepared with the same quantity of silver halide).

Experiment 3.—Further analysis of the alcohol-ether extract of plasma

A sample of plasma was extracted with alcohol-ether. The extract was divided into two portions. These were treated as follows:

(a) *Isolation of ionic iodine from alcohol-ether extract:*

To one portion nitric acid, carrier sodium iodide, and silver nitrate in aqueous solution were added in that order. The yellow precipitate was collected, dried, and washed thoroughly with ether and petroleum ether. The halide fraction contained 25-30% of the radioactivity of the alcohol-ether extract.

(b) *Isolation of ionic iodine from lipid-free alcohol-ether extract:*

Another portion was evaporated to dryness and extracted with water. Silver halides precipitated from the extract contained approximately 10% of the total activity.

Experiment 4.—Analysis of the protein and lipid-free filtrate of plasma

Protein was precipitated with sodium tungstate from an aliquot of plasma by the method of Folin and Wu (21). The filtrate was evaporated to dryness, extracted with ether and the residue dissolved in water and filtered. Ionic iodine was precipitated with silver nitrate as above. The precipitate of silver chloride and silver iodide was collected, washed thoroughly with water, acetone, and ether, and its radioactivity determined. The protein precipitate had no measurable radioactivity. The silver precipitate (*i.e.*, presumably the ionic iodine fraction) contained 15-20% of the activity in plasma.

The results for fractions extracted by organic solvents are somewhat high (error approximately 15%) and those for the silver halide precipitates somewhat low (error approximately 10-20%), because of differences in the dry weights of these samples as compared with standard plasma specimens. Corrections were not made for such variations in weight except to determine the per cent of error given above by suitable control experiments.

These experiments (Table II) show that 24 hours after the injection of the emulsion approximately 60% of the circulating plasma radioactivity was in the total lipid fraction and approximately

Radioactivity circulating in fractions of plasma of dogs
24 hours after injection of radioactive fat emulsion,
expressed in per cent of the activity
in the circulating plasma

Experi- ment no.*	Lipoid fraction	Per cent of radioactivity in circulating plasma			
		Inorganic fraction		Protein	Phospho- lipid
		Precipitated with silver	Insoluble in organic sol- vents but soluble in H ₂ O		
1	%	%	%	%	%
2	50-65	9-12†	20	0	0
3a	60	25-30†			
3b		10			
4		15-20†		0	

* The results listed for each type of experiment were obtained from two to four experiments.
† These samples contained silver chloride in addition to silver iodide.
‡ These samples may have contained the silver salt of radioactive fatty acid.

20% was in the water soluble residue, free of lipid and protein (Experiments 2 and 4). The value, 9-12%, is a low estimate of what was present as ionic iodine (Experiment 3b). In a pilot experiment this discrepancy of 11-8% was accounted for by the self-absorption of β -rays by the heavy mass of the silver precipitate. Part of

the 25-30% radioactivity in the silver halides precipitated from an alcohol-ether extract (Experiment 3a) may be due to radioactive fatty acids carried down with the halides.

Tissue Distribution of Radioactivity After Injection of Fat Emulsion

A. In Dogs

Tissue analyses for radioactivity by methods previously described (1) were performed in five dogs sacrificed by exsanguination at various intervals after injection of the emulsion.

The results, listed in Table III, are expressed in (1) activity per organ in per cent of the total activity injected, and (2) activity of 1 gm. of tissue in per cent of activity circulating at zero time in 1 cc. of plasma, assuming the plasma volume of each dog to be 5% of the body weight.

Samples (1 gm.) of various tissues when wet did not yield dry tissues of uniform weight. Error was thus introduced into the radioactivity measurements by difference in self-absorption of β -rays. However, the dry weight of any given tissue from one animal to another was remarkably uniform and changes in the radioactivity of any given tissue with time could be reliably compared (22).

injection, the liver, lungs, plasma, muscle and spleen, in decreasing order, contained the largest fractions of the total radioactivity. Mesenteric fat and thyroid showed the lowest radioactivity content of all tissues examined. Some 41% of the total radioactivity injected was recovered in the tissues examined.

In Dog 24, sacrificed two days after injection, only 17% of the total radioactivity injected was recovered in these same tissues. The same amount was recovered from the same tissues in Dog 21, sacrificed five days after injection. In Dog 23, sacrificed ten days after injection, only some 2% of the amount injected was found in these tissues.

The spleen, lungs and liver, in decreasing order, showed the highest specific radioactivity one day after injection (Dog 22). The same was true after two days (Dog 24) although a substantial decline was obvious in all these organs, while the thyroid showed a very large increase in specific activity. This was all the more striking after five days (Dog 21). The spleen exhibited the slowest decline in specific activity. The continuously very low total and specific radioactivity of

mesenteric fat is noteworthy. This is all the more so, in view of the fact that every other tissue studied showed a higher specific activity, at least during the first five days after injection. Ten days after injection very little activity was found in any of the tissues except the thyroid.

Specimens of urine were collected at various intervals after injection. The total urine collected in one of the dogs (Dog 20) during the first eight hours following injection contained 2½% of the total activity injected. By the third day, the specific³ activity of the urine averaged 0.5% in all dogs. It remained at that level for the duration of the experiment in Dogs 20, 21 and 23.

B. In Mice
